GRESHAM COLLEGE.

MR. GOSCHEN—speaking on behalf of the London Branch of the Lecture Society which was started by Prof. James Stewart, of Cambridge, for the purpose of giving remunerative employment to some of the younger graduates of Oxford and Cambridge, and at the same time of affording instruction and amusement of an intelligent character to such audiences as the larger manufacturing towns afford—has publicly urged the claim of the Society to enter upon Gresham's heritage, and by the aid of the funds still in the hands of his trustees, and of such moneys as those trustees may think it incumbent upon them to restore to the Gresham trust, to carry out the purpose of that great founder, who, two hundred and fifty years ago, bequeathed property, now valued at several millions sterling, for the purpose of maintaining a College of Professors in London. There is no question as to what were the intentions of Gresham, nor as to the disgraceful nature of the transactions by which his trustees—the Corporation of London and the Mercers' Company—a little more than one hundred years ago were enabled to seize the property of the trust, and, with the sanction of an Act of Parliament, to assign a mere fraction of it to the payment of half a dozen lecturers, whilst appropriating the bulk of it to their individual and corporate use.

It is beyond question that the existing representatives of the Corporation of London and the Mercers' Company are ashamed of the neglect and spoliation of which their predecessors, in a corrupt age, were guilty. They would be glad to assign the money with which they at present pay so-called "Gresham Professors," and even a large additional sum, representing the misappropriated trust funds, to an institution more truly representing Gresham's purpose than the lecture-room now existing at the back of Mercers' Hall, in the heart of the City, could they be assured that any one of the various plans which have been from time to time urged upon them was really a wise and true method of carrying out that purpose.

We venture to think that Mr. Goschen has merely added to the perplexity in which Gresham's trustees find themselves by his ill-timed proposal that his Lecture Society should be supported by the funds disposed of by those trustees. The lectures given by this Society are, we feel assured, excellent in their way, and we do not doubt that they give a large amount of pleasure and of useful information to the persons who attend them. We are aware that the lectures are more serious in scope than the series of popular lectures frequently arranged by lecture associations, and consist of short courses, in which one teacher is able at some length to explain the outlines of his subject, instead of isolated lectures by numerous individuals on disconnected topics. It is only reasonable that any public or semi-public institution, having a lecture-theatre at its disposal, should encourage so excellent a Lecture Society as Mr. Goschen's, by giving it the use of rooms from time to time. Thus the various Vestry Halls of London may be (and we believe have been) made use of. The London Institution in Finsbury Circus, University and King's Colleges, and the University of London could easily lend a lecture-theatre from time to time to Mr. Goschen's *protégés* as they have to other similar Societies. And it is not unfitting that Gresham's trustees should lend the little-used theatre of the Gresham Professors for the same purpose. When, however, Mr. Goschen and his friends take advantage of this hospitality to urge that not only should Gresham's theatre be lent to them, but that Gresham's money should be assigned to the support of their lecturers, it seems to us that an unwarrantable pretension is put forward, and one which is to be deprecated on very special grounds. Those grounds are as follows.

Gresham's foundation was assigned by him to the support of a body consisting of seven learned men, to whom he proposed to furnish, not a mere fee for a short course of lectures, but a life-provision—in fact, a residence, laboratories, and the means of research, as well as a stipend, at the highest rate at which such persons were paid three hundred years ago, as shown by the payments made to the Professors and College officials of Oxford and Cambridge. Gresham assigned his own palace and garden, situated where Old Broad Street at present runs,

for the dwelling-place of the Professors of his College; and here the first Gresham Professors did reside, and not merely give instruction to the citizens of London by means of lectures, but—what was far more important—carried on their studies and researches. Here the Royal Society met in its early days, and here, in fact, were the head-quarters of learning and science in London.

It is clear enough that what Gresham intended to found, and what actually was constituted by his trustees in the year 1596, was an institution similar to the Professorial Universities of Scotland and Germany of the present day. He distinctly founded seven Professorships—viz. of Physic, Law, Rhetoric, Geometry, Music, Astronomy, and Divinity—and ordered that the proceeds of the rents derived from the shops and houses around the Royal Exchange which were his property should be used in paying each of these Professors £50 a year—no small sum at that time, since the yearly value of Gresham House itself and the gardens attaching to it was, at the date of Lady Anne Gresham's death, in 1596, estimated at only £67!

In view of these facts, it is idle to pretend that the Lecture Society has any similarity to the institution designed by Gresham. Whatever good Mr. Goschen's Lecture Society is doing, it is not doing the work which Gresham intended his College to perform, although Mr. Goschen tells us that he thinks that it is.

To subsidize a series of innumerable short courses of lectures by innumerable young men of small experience is a totally different thing from housing and providing for life seven chosen teachers—the best, the most skilled, the most original in discovery, the most masterly in discourse, worthy to represent science and learning in this great city of London.

By the former course you may diffuse a little knowledge amongst a great many people who will not themselves pay for the pleasure thus presented to them. This is Mr. Goschen's plan. By the second you hold before younger men a prize to stimulate their endeavours; to the matured and chosen teacher you give the leisure and security necessary for research—that is, for the making of new knowledge; to the citizens of London you assure the presence in their midst, and the continual teaching, of the ablest discoverers and philosophers. That is Gresham's plan.

It may be, and, indeed, has been, argued that it is impossible to carry out Gresham's plan, and that the best thing to do with whatever can be got together of his trust funds is to administer it on the principle of *çy-près*, and, accordingly, to let Mr. Goschen's Society have it.

To this we reply that Mr. Goschen's Society has no claim whatever upon this principle, since there are institutions in London—namely, University and King's Colleges—which come near to realizing Gresham's intentions, and if endowed by his funds would actually realize them, whilst Mr. Goschen's Society is as different from Gresham's College as a pic-nic is from a military expedition. A very objectionable use is made of the word "University" in the endeavour to gain support for the Lecture Society. It is spoken of as a "Society for the Extension of University Teaching," and more briefly as "University Extension." The implication is that the teaching is such as is given at Universities, and it is an entirely false implication. The teaching given at Universities depends for its character on two chief factors—firstly, the selection and consequent ability of the teacher; and secondly, the continuous and entire devotion of the student's time to the training and instruction provided for him. In both these factors the Lecture Society differs *toto cœlo* from even the most eccentric University, and has no claim to employ that much misused term. Yet it is by taking advantage of the misconception created by its use in connection with the Lecture Society that a claim has been made for this Society both to take part in the organization of a new University of London and to benefit by Gresham's trust, which it is rightly alleged was intended for the introduction into London of University teaching.

If the present representatives of Gresham's trustees—the Corporation of London and the Mercers' Company—would simply carry out the provisions of his will as nearly as possible—much as they were carried out in the year 1596—all would be well, and the contentions of rival claimants to a share of the pickings still to be got from the bones of Gresham College would be silenced.

The original Gresham College began well enough, and caused the greatest satisfaction to the citizens of London. The lectures were largely attended, the Professors were men of great distinction, and a long and useful career was foreseen for the College. A similar institution—the Collège de France—was founded in Paris by the French King about the same time. The Collège de France exists to this day, and is one of the most effective and valuable institutions in the world for the production of new knowledge.

Our London College perished simply and solely through deliberate jobbery and corruption. The trustees purposely neglected their trust; incompetent persons were appointed by them to the Professorships; they themselves stole the land round about Gresham House, and excused the Professors from lecturing in order to avoid prosecution by the Professors for arrears of salary. In the beginning of the eighteenth century Gresham College was an object of contempt and derision to the citizens of London. The trustees had ruthlessly and systematically plundered the trust-funds and prostituted the Professorships, so that no one raised even a feeble protest when the work of perfidy was consummated, and Gresham House was pulled down, the site handed over to the Excise Office, and the worshipful trustees were spared all responsibility as to their dealings with property worth some millions at the present day, in consideration of a payment of £500 a year.

There are those who maintain that, were Gresham College reconstituted at the present day, it would have the same fate. We are not disposed to believe this. It was, no doubt, a mistake on Gresham's part to place such absolute confidence as he did in the Corporation of London and the Mercers' Company. We have invented, since Gresham's time, methods for keeping a check on erratic trustees; but what is of far greater importance is, that at the present time there is a real and earnest desire on the part of the great City Companies to do service to the State and honour to themselves by employing the funds in their possession for the good of the community. It is not improbable that—were a scheme for the establishment of a thoroughgoing Professorial University in London

(similar in its aims and methods to Gresham's College, and by no means similar to Mr. Goschen's Lecture Society) forthcoming as the result of the deliberations of the Royal Commission now sitting to consider the question of the future University of London—the present representatives of Gresham's trustees would be willing and anxious to redeem the past by endowing in that University seven or more Gresham Professorships, with a sum representing in adequate degree the property long ago misappropriated by their predecessors. Sir Thomas Gresham, the greatest and most generous of merchants who ever desired to benefit the City where he lived and prospered, the man who, above all others, has been most shamefully betrayed by those whom he trusted and loaded with gifts, may yet be honoured and justly dealt with. It rests with the Corporation of London, and the Worshipful Company of Mercers, to give to the future University of London, Gresham's name and Gresham's money.

E. RAY LANKESTER.

BACON.

Bacon. By R. W. Church, Dean of St. Paul's. (London: Macmillan and Co., 1888.)

THE handsome volume before us, which forms the fifth volume of Dean Church's collected works, is a reprint (with, apparently, few or no alterations) of the small book on "Bacon," which originally appeared in Mr. Morley's series of "English Men of Letters." Like every literary composition which falls from the pen of its author, it is a model of candour in treatment, and of gracefulness in style. Other accounts of Bacon may be more profound, more detailed, or more appreciative, but certainly none is likely to be more interesting or attractive to the general reader.

The early chapters, constituting the larger portion of the book, are occupied with Bacon's life, and therefore, by implication, with the never-ceasing controversy about his character, conduct, and motives. On these topics, Dean Church's judgment decidedly inclines to the side of severity; nor does he, as it seems to us, make sufficient allowance for the temptations to which Bacon was exposed, arising largely from his financial embarrassments, the peculiarly difficult positions in which, as in the case of Essex, he was sometimes placed, or the habits and circumstances, so different in many respects from our own, of the times and circles in which he lived. At the same time, the sentence, however decisive, is always delivered in kindly and gentle tones, as that of a judge who regrets, rather than denounces, the faults which he condemns. The judgments of Dean Church, even when we regard them as erroneous, always demand our attention, and perhaps all the more so, because they are entirely free from the asperity and ferocity of tone which mark the utterances of some others of Bacon's more recent critics.

But our business is not so much with the chapters on Bacon's life and character as with the chapter on his philosophy. Here Dr. Church mainly follows the lead of M. de Rémusat, and consequently his account, though reflective and suggestive, and often singularly felicitous in expression, appears to us to be wanting in the definiteness and precision which are requisite in the estimate of a philosophical or logical system. He does not, for instance, bring out with sufficient emphasis the fact that Bacon was what in our own days we should call, not a philosopher, but a logician. His mission, as Bacon himself conceived it, was to bring about a thorough reform in the method of science, and through this new method to reconstitute, or, rather, to enable others to reconstitute, from their very foundations, the whole circle of the sciences—moral, mental, and political, as well as what are more strictly called natural. The inductive method was not conceived of by Bacon as antagonistic to the deductive method, but as its necessary antecedent and complement. Nor did he regard himself, nor would it be right to regard him, as the inventor of the inductive method, any more than Aristotle regarded himself, or it would be right to regard him, as the inventor of the deductive method. What both philosophers alike did, was to analyze, classify, and discriminate, with a view to distinguish between correct and incorrect reasoning, the methods of natural logic already in use. Only, while Aristotle performed this work effectively, and, considering the time at which he taught, with marvellous elaboration, for the syllogistic logic, he did little more than point out the existence and necessity of induction. This want of rules and of a sufficient analysis of the inductive side of reasoning easily accounts for the utterly unscientific character of the inductions with which men ordinarily satisfied themselves throughout the Classical and Middle Ages. What really constituted the most distinctive feature in Bacon's conception of a reformed logic was the profound idea that induction, instead of being the loose, vague, and uncertain process which was then in vogue, admitted of being presented with the force of demonstration, and thereby, if the facts on which it was founded were true, of supplying as firm a basis for the premises, as the premises, if they were true, supplied for the conclusion of the syllogism. "Inductionem enim censemus eam esse demonstrandi formam, quæ sensum tuetur et naturam premit et operibus imminet ac fere immiscetur" ("Distributio Operis"). "Verum ad hujus inductionis, sive demonstrationis, instructionem bonam et legitimam quamplurima adhibenda sunt, quæ adhuc nullius mortalium cogitationem subiere; adeo ut in ea major sit consumenda opera, quam adhuc consumpta est in syllogismo" ("Novum Organum," Book I. Aph. 105). Thus it is hardly an exaggeration to say that inductive logic—that is, the systematic analysis and arrangement of inductive evidence, as distinct from the natural induction which all men practise—was almost as much the creation of Bacon as deductive logic was that of Aristotle. Dean Church rightly calls attention to the wide interval which separates Bacon's "Tables of Instances" from the experimental methods of Mr. Mill; but the latter are, after all, only a corrected version of the former, and, historically, were derived from them through the medium of Sir John Herschel's discourse on "The Study of Natural Philosophy." Moreover, it is remarkable that the two divisions of the "Instantiæ Solitariæ," described in "Nov. Org.," Book II., Aph. 22, correspond respectively with Mill's "Methods of Agreement and Difference," and that the very words "method of agreement" and "method of difference" all but occur in the text. For these and many similar reasons, we certainly cannot

accept the verdict of Dean Church, that "the course which he marked out so laboriously and so ingeniously for induction to follow was one which was found to be impracticable, and as barren of results as those deductive philosophies on which he lavished his scorn." This remark may be approximately true of the method of rejections or exclusions, which proceeds on the false assumption that the whole complex system of the material universe may be resolved into a small and definite number of "simple natures," just as the numerous words which constitute a language may all be resolved into the few and assignable letters of an alphabet; but it is most emphatically not true of the methods which are subsidiary to the method of exclusions, such as the "Tables" and "Prerogatives of Instances." The subsidiary methods have, happily, a value of their own quite independently of the main object which they were supposed to subserve. Nor, as it seems to us, can it be doubted that these methods have been actually fertile in the progress of scientific discovery. Not, perhaps, that the greatest discoverers have often consciously, deliberately, and designedly set to work to employ them; but methods and principles of this kind, when once enunciated and realized, are, as it were, "in the air," and their influence is often no less potent because it is one of which men are only dimly conscious.

The process of fault-finding, especially as applied to a book which we have read with interest and pleasure, is not one which we would gladly prolong; but, to prevent a very grave misconception of Bacon's philosophical position, we feel it incumbent on us to point out a serious error into which Dean Church has been led by too implicit confidence in the authority of Mr. Ellis. "Bacon's conception of philosophy," we are told, "was so narrow as to exclude one of its greatest domains; for, says Mr. Ellis, 'it cannot be denied that to Bacon all sound philosophy seemed to be included in what we now call the natural sciences.'" By "sound philosophy" is meant, it may be presumed, philosophy based on experience, and arrived at by the inductive method. In "Nov. Org.," Book I., Aph. 127, we have the question as to the range of the sciences to which the new method is applicable definitely propounded and definitely answered. "Etiam dubitabit quispiam potius quam objiciet, utrum nos de Naturali tantum Philosophia, an etiam de scientiis reliquis, Logicis, Ethicis, Politicis, secundum viam nostram perficiendis loquamur. At nos certe de universis hæc quæ dicta sunt intelligimus: atque quemadmodum vulgaris logica, quæ regit res per syllogismum, non tantum ad naturales, sed ad omnes scientias pertinet; ita et nostra, quæ procedit per inductionem, omnia complectitur." There are many other passages in the "Novum Organum," the "De Augmentis," and elsewhere, to the same effect. Indeed, it appears to us unquestionable that Bacon, while he regarded his method as primarily, and, perhaps, most easily, applicable to the natural sciences, contemplated its ultimate extension to all branches of knowledge alike. The few passages which seem to point in the opposite direction are, doubtless, ironical, and refer, not to science, or knowledge in the true sense, at all, but to rhetoric and disputation.

The last chapter of the book is on Bacon as a writer. Here the author is thoroughly at home, and the striking and suggestive remarks which he makes on this topic only cause us to regret that there are not more of them. Take, for instance, the following just and forcible sentences on Bacon's English composition:—"His manner of writing depends, not on a style, or a studied or acquired habit, but on the nature of the task which he has in hand. Everywhere his matter is close to his words, and governs, dominates, informs his words. No one in England before had so much as he had the power to say what he wanted to say, and exactly as he wanted to say it. No one was so little at the mercy of conventional language or customary rhetoric, except when he persuaded himself that he had to submit to those necessities of flattery, which cost him at last so dear."

T. FOWLER.

KARYOKINESIS.

Ueber Kern- und Zelltheilung im Pflanzenreiche, nebst einem Anhang über Befruchtung. Von E. Strasburger, o. ö. Professor der Botanik an der Universität Bonn. Mit drei lithographischen Tafeln. (Jena: Gustav Fischer, 1888).

PROF. STRASBURGER intends this volume to constitute only the first of a new series of contributions to our knowledge of vegetable histology. In these 258 pages the phenomena attending indirect or mitotic nuclear division, and the earlier stages in the formation of the cell-membrane, are entered on in detail. During the four years which have elapsed since the appearance of the author's last contribution to this subject ("Die Controversen," &c.) numerous memoirs have been published relating to the nucleus and its division. Prof. Strasburger not only contributes a vast number of new facts, but also reviews the whole nuclear question in a masterly fashion, so that the work may be regarded as a critical text-book of our present knowledge of the subject. It will be seen from what follows, that, although many of his former conceptions have been confirmed, there still remain points which are doubtful, and some positions formerly held by him which are now abandoned.

The book commences with a long account of a renewed investigation of the nuclear processes in *Spirogyra*, the research in question being carried out on a new species, *S. polytæniata*, which presented many facilities for the purpose. This account is full of interest, but difficult to do justice to here, without figures. During the early stages of division, whilst the nuclear fibrils are making their way to the equatorial plane and the nucleolus undergoing solution, but before the breaking down of the nuclear wall, a mass of cytoplasm is formed on the two faces of the nucleus which are directed towards the end-walls of the cell, and in these a striation becomes apparent, representing the commencement of the spindle. Soon the nuclear wall becomes indistinct where the striation abuts upon it, and spindle-filaments appear within the nucleus; these form an undoubted continuation of those which appeared outside. There would appear to be no ground for supposing these later-appearing filaments of the spindle to have an origin differing from those which appeared first of all, but rather they are their direct continuation, and due to the intrusion of cytoplasm into the nucleus.

It is the view of the author that in this, and in all other cases, the spindle has a cytoplasmic origin, and this is in agreement with his former tenets. The occurrence of an almost complete spindle within the nucleus in *S. nitida*, before the break-down of the nuclear wall, is shown to be very probably due to the entrance of cytoplasm through a number of small pores; since the wall, as seen in its polar aspect, shows a sieve-like dotting from which a perforation is inferred. The event in *S. nitida* differs thus only in degree from that in *S. polytæniata*. Throughout the whole process of division the nucleus is enclosed in a cytoplasmic mantle or pocket, which is suspended freely in the cell-lumen by delicate protoplasmic filaments. As the two halves of the nuclear plate separate, a cavity is formed—at first traversed by the uniting-filaments (*Verbindungsfäden*)—which increases in size by a continuous absorption of fluid through its wall, and is regarded by the author as a mechanism by means of which the two young daughter-nuclei are driven apart. For further details the reader is referred to the original, and to the figures on Plate I.

We pass on now to the typical events in the nucleus of higher plants. In the "resting nucleus" (used in the conventional sense only, in contradistinction to "dividing nucleus") there exists a definite, limiting layer, the nuclear wall, which consists undoubtedly of cytoplasm. The nuclear reticulum consists of a number of fibrils so interwoven that it is difficult to say whether they have fused into a genuine network, or really retain their individuality, and are simply in contact with one another. The author is distinctly of the opinion that the latter is the case, and that after a division the nuclear segments or fibrils remain separate, never losing their individuality. The probability of this view is greatly increased by the constancy in number of these fibrils as shown especially by investigation of division-stages of pollen-mother-cells in Liliaceæ. The number of segments is very commonly sixteen, the relatively high number obtaining in developing endosperm-cells being due to the fusion of the two nuclei, which gave rise to the secondary nucleus of the embryo-sac. Thus, in the endosperm of *Lilium Martagon*, Guignard found twenty-four or more segments, though but twelve or sixteen in the daughter-nuclei of the primary embryo-sac nucleus. Although information on this head is limited, it has been shown that where a sudden considerable increase in the number of segments has been observed there has been a previous fusion of nuclei, as often occurs in the young endosperm cells of *Corydalis pallida*. A slight increase, however, may often be due to better nutrition. Absolute constancy in number of segments is only met with in the case of generative nuclei, so far as investigation as yet shows.

Lying between the fibrils, and adhering to them, are one or two nucleoli. Bathing the fibrils and nucleoli is the nuclear sap, which at this period is not stainable. The fibrils consist of a non-staining substance, the nucleo-hyaloplasm, in which are embedded a number of irregular, strongly-staining granules, the chromatin-granules. The author prefers to speak of the nucleo-hyaloplasm, with Schwarz, as Linin. The name nucleo-microsomata for these chromatin-granules is here definitely abandoned, as there exists no true parallel between them and the microsomata of the cell-protoplasm. In the resting vegetable nucleus Prof. Strasburger finds no trace of the faintly staining "bridges" described by Flemming and Rabl as uniting the nuclear fibrils in the Salamander. When division is about to take place a shortening of the nuclear fibrils occurs, accompanied by a definite increase in thickness. The chromatin-granules at the same time run together into plates, separated from one another by linin (nucleo-hyaloplasm). These plates of chromatin grow at the expense of the linin. The fact, that this takes place in *Fritillaria* before the disappearance of the nucleoli, precludes the possibility that the chromatin grows at the expense of the nucleoli. It is probable that this equal distribution of substance in the nuclear fibrils insures completely similar products when the subsequent longitudinal fission takes place.

The dividing nucleus now enters on the "skein-phase," and the arrangement of the fibrils may be seen with distinctness. At this period in many nuclei—as, for instance, in the young endosperm of *Fritillaria imperialis*—the separate segments lie, for the most part, parallel, each segment being loop-shaped with legs of approximately equal length. The points of bending converge on one side of the nucleus—its polar side; the free ends terminate towards the antipolar side. The polar side of the nucleus would appear to bear a definite relation to the point of convergence of the daughter-segments of the previous division, and generally the line joining the polar and antipolar sides will cut the nuclear plate at right angles. It is during this stage that the nucleoli disappear. Hitherto they have occupied an eccentric position, lying it would seem towards the polar side—this being the region least occupied by nuclear fibrils. As the nucleoli disappear, the nuclear sap becomes capable of staining, and the inference is that this is due to the presence in the sap of the dissolved nucleolar matter. The author regards it as improbable that the nucleoli go to nourish the nuclear fibrils. The structures to which Prof. Strasburger formerly gave the name of paranucleoli, he now acknowledges to be simply nucleoli late in disappearing, so that all the theoretical deductions based on the appearance of those structures, by the author and others, fall to the ground.

The nuclear membrane now breaks down, the segments place themselves in the equatorial plane forming the nuclear plate, and the spindle makes its appearance. The author at great length details the evidence in favour of the cytoplasmic origin of this structure, but into this we cannot enter here. The poles of the spindle are determined before the solution of the nuclear wall, but they do not influence the nuclear fibrils in their transpositions before the breaking down of the wall. It must not, however, be concluded from this that the changes within the nucleus are entirely independent of the cytoplasm until the end of the skein-phase. The division of nuclei within the embryo-sac, which is almost simultaneous, would negative such a view. The cytoplasm does not exert any directive influence on the fibrils until the breaking down of the wall. The fibrils now depend for support on the filaments of the spindle, and these are generally equal in number to the segments—one to each, or, after the fission of the segments, one to each segment-pair. The completion of transposition and the separation of the segment halves are carried out under the influence of the spindle, a certain directive action of the poles being exerted; the segments

themselves are not passive, but possess a movement of their own held in control by polar influences.

For details relating to the complicated transpositions of the fibrils, their longitudinal fission, and subsequent separation, the reader is referred to Chapters VII. and VIII.

The two groups of daughter-segments separate, the segments travelling along the filaments of the spindle. Prof. Strasburger considers the hypothesis that the travelling is due to streaming of the protoplasm improbable, as this would involve the running of two opposite currents in each spindle-filament. Further, no streaming, either in or on the filaments, has been observed in the living, dividing nucleus. The fibrils themselves probably possess a capacity for movement, using the spindle-filaments only as supports. What stimulus the segments may receive from the poles is difficult to say—perhaps one similar to the chemical stimulus which causes directive movements in Bacteria, Plasmodia, &c. As the groups of daughter-segments move apart, the spindle-filaments, which are continuous from pole to pole, on the view of Strasburger, are seen stretching over the interval. These constitute the primary uniting-filaments, and there is some diversity of opinion as to their origin. Soon, more cytoplasm makes its way into the equatorial region, and a great increase in the number of the filaments takes place. These additional, or secondary, uniting-filaments are formed from this intrusive cytoplasm, and not by multiplication of the primary ones.

The nuclear sap, and dissolved nucleoli, lie between the uniting-filaments; and even after the collection together of the daughter-segments to form the daughter-nuclei, there remains a considerable residuum of stainable nuclear sap which makes its way to the equatorial region of the spindle and appears to play a most important part.

At this moment a small bead-like thickening appears on each uniting-filament—both primary and secondary—in the equatorial plane, and it is by the fusion of all these thickenings that the cell-plate or primitive cell-membrane arises. Throughout, Prof. Strasburger speaks of this occurrence with the greatest confidence, in opposition to the view of Zacharias and Flemming. These swellings which constitute the elements of the cell-plate, are spoken of as *dermatosomata*, although the same word has been recently used by Weisner with another significance. Fresh uniting-filaments continue to arise at the periphery of the young cell-plate, each bearing a local swelling (*dermatosome*), and in this manner the cell-plate is completed.

In cases of free-cell-formation a temporary cell-plate appears, but is not completed, and subsequently disappears.

It is at this stage that Prof. Strasburger attaches great importance to the part played by the stainable nuclear sap. As above mentioned, a portion of this has collected in the equatorial region, and everywhere bathes the dermatosomata. At the same time a demonstrable change takes place in their constitution; the dermatosomata offer a greater resistance to such a reagent as *eau-de-javelle*, and show an increased refrangibility. In other words, the cell-plate has been converted into the first layer of the new cell-wall. These changes are traced to the stainable nuclear sap which is present. A direct proof of this is very difficult, but the hypothesis is a most taking one; accounting, as it does, for a number of phenomena which have long baffled explanation; and it possesses also the added charm of simplicity. The chief objection to this theory is the difficulty in imagining the continued presence of the nuclear sap in regions where the cell-wall is undergoing a thickening; for will not the process of conversion throughout be identical, whether it be primary or secondary layers that are being formed? Perhaps in a future contribution this will be explained; but for the present this hypothesis must remain a hypothesis, and will—be it hoped—stimulate investigation into a matter on which more light is much needed.

As the daughter-nuclei are formed, a considerable portion of the nuclear sap is taken in, and lies, in the first instance, on the antipolar side of the nucleus, where in some few cases (embryo-sac of *Hyacinthus orientalis*) the nucleoli appear, and the sap loses its staining property. In the majority of cases the nucleoli, as stated above, appear towards the polar side.

In a chapter dealing with the function of the nucleus the view is put forward that it has the same relation to starch-formation as very probably exists between it and the development of cell-membrane. The fact that Klebs found, in plasmolyzed filaments of *Spirogyra*, a formation of starch occurring in masses of protoplasm destitute of a nucleus, Prof. Strasburger considers due to the fact that the pyrenoids physiologically replace the nucleus in this connection. This finds support in the fact that in plasmolyzed cells of *Funaria* the chlorophyll-corpuscles in fragments of cells without a nucleus are unable to form starch.

The book concludes with a chapter on fertilization, in which controversial matters are discussed. The author adheres to his former view that in higher plants fertilization consists of the fusion of an equal number of nuclear segments, as also of the nuclear sap of the two conjugating nuclei. He finds no evidence for the view of Zacharias that the male and female nuclei differ essentially in any way.

It is impossible here to do full justice to this remarkable book, and there are many matters traversed in it to which we have not even alluded. Thus, the detailed comparison drawn between the vegetable and the animal nucleus. It seems that the differences in this respect occurring between lower and higher plants find their parallel in comparable differences in more lowly and more highly organized animals.

A careful perusal of the original will repay the labour so expended, and the style and arrangement of the subject-matter are such as to make us unwillingly lay it aside. Perhaps some idea of the pace at which knowledge in minute cell-histology has progressed may be obtained when we remember that only seventeen years ago a botanist, who now stands in the foremost rank of plant-histologists, was prepared to maintain as a thesis, and to dispute with all comers, "that in the vegetable kingdom nuclear division does not occur." F. W. O.

OUR BOOK SHELF.

Chambers's Encyclopædia; a Dictionary of Useful Knowledge. New Edition. Vol. II. (London and Edinburgh: W. and R. Chambers, 1888.)

THE second volume of the new edition of "Chambers's Encyclopædia," which extends from "Beaugency" to "Cataract," maintains the high standard set by the

first volume. The names of the writers are a guarantee for the excellence of the work; and, where not wholly rewritten, the articles have been revised and brought up to date. Mr. J. Arthur Thomson is responsible for the zoological articles, which in this volume are Bee (in which Sir John Lubbock has assisted), Bird, and Butterfly; Mr. Patrick Geddes is the writer of the articles on Biology, Botany, Bud; Dr. W. Inglis Clark writes on Carbon, Prof. James Geikie on the Carboniferous System, Prof. Wm. Thomson on Capillarity, and Mr. A. Fraser on the Calculus. The articles on engineering and architectural subjects are contributed by Messrs. D. and T. Stevenson, D. K. Clark, and David MacGibbon. In geography, Sir Charles Warren writes on Bechuanaland, Sir Charles Bernard on Burmah, Mr. S. Lane-Poole on Cairo, Mr. Macdonald, of the *Englishman*, on Calcutta, Prince Kropotkine on the Caspian Sea. Amongst other geographical articles are those on Belfast by Mr. T. Macknight, Birmingham by Mr. S. Barnes, Bolivia by Mr. W. Dundus Walker, Bristol by the Rev. W. Hunt, Brittany by Mr. Thos. Davidson, Bulgaria by Mr. A. Silva White, Cambridge by Mr. G. H. Smith, Canada by Mr. J. G. Colmer, C.M.G., Cape Colony by the Rev. J. Mackenzie, and Cashmere by Major Holdich. Five excellent maps accompany this volume—namely, (1) Belgium; (2) Burmah, Siam, and Assam; (3) Canada, Eastern Provinces; (4) Canada, Dominion of; (5) Cape Colony and South Africa. The less important articles are also very satisfactory. For those who desire further information on the various subjects a list of authorities is given. Many of the articles are models of compression. The article on Carlyle is an instance of this. Here the large and growing literature relating to Carlyle, published since his death, is compressed into the space available in a manner that is little short of amazing. In this and one or two articles which we have noticed, the very difficult art of saying much in a little space, of reducing volumes to paragraphs, and even to lines, is exhibited in a high degree of excellence.

Star Atlas, containing Maps of all Stars from 1 *to* 6·5 *Magnitude between the North Pole and* 34° *South Declination, and all Nebulæ and Star-clusters in the same Region, which are visible in Telescopes of moderate powers, with Explanatory Text.* By Dr. Hermann J. Klein. Translated and adapted for English readers by Edmund M'Clure, M.A., M.R.I.A. (London: Society for Promoting Christian Knowledge, 1888.)

THIS is a most important addition to the stock-in trade of the amateur astronomer. The eighteen maps, printed by Funke, of Leipzig, are as clear as they can be, the letters and constellation boundaries being given in red ink.

There are some useful tables given in the introduction, and these are followed by a catalogue of the most interesting objects, which seem to have been very carefully chosen by a practical astronomer, and the editor has done his best to bring the accompanying notes down to the latest date.

In addition to the maps, some excellent illustrations of clusters and nebulæ are given, and no pains have been spared to give as much useful and trustworthy information as possible.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Alpine Haze.

FOR some years past, occurrences in the Alpine atmosphere have frequently reminded me of effects produced in the "experimental tubes" with which I worked some years ago. When the experimental tube was already occupied by a fine "actinic cloud," it was a common experiment to precipitate within the tube an ordinary cloud by dilatation. The melting away of this latter, and the reappearance of the finer and more persistent cloud, which it had for a short time disguised, were curious and instructive effects.

In the valleys of the Alps floats, not unfrequently, a fine haze, much resembling the actinic clouds. This year the haze was more than usually prevalent, being sometimes very curiously distributed. It frequently filled the great Rhone Basin, below Alp Lusgen. Amid the haze, patches of true cloud would appear, extending till they became continuous, and filled the basin. A floor of cloud, usually shining white, would then spread below us. Under a strong sun, the cloud would disappear, leaving the more permanent haze behind. The haze could not have been aqueous. I have seen the dense true cloud disappear early in the morning, and the haze continue through a fervid summer day, until the moon came out at night to illuminate it. The distribution of the haze this year, and the consequent precipitation were often remarkable. Looked at from our eminence, the haze would be seen filling the lower valley, but divided above into long horizontal striæ, which were obviously the edges of haze-layers, foreshortened from our point of view. Mr. Stirling's beautiful observations were frequently brought to mind by the obvious tendency of the aqueous clouds to form in, and to follow, the haze. A highly picturesque distribution of the clouds was often thus produced. What the haze *is* I do not, for a certainty, know; but that it is not water is proved by its persistence in presence of a powerful sun, and above the heated earth-surface. The late Prof. De la Rive would probably have referred it to floating germs (see letter to myself "On the Organic Dust of the Air," *Phil. Mag.*, 1870, vol. xxxix. p. 229). The prevalence of autumn pollen in the air may, perhaps, account for the singularly striking cloud effects invariably observed at Alp Lusgen, at the end of September and the beginning of October.

JOHN TYNDALL.

Hind Head, Haslemere, October 30.

Prophetic Germs.

MY desire in this controversy has been to bring the Duke of Argyll's theory to the test of fact. But I cannot obtain from him any statement of fact which tends to support his belief in prophetic germs. He cites the well-known observation that in the growth of the individual from the egg, organs pass through rudimentary stages, during which they are not used He then says: "On the Darwinian hypothesis this fact applies equally to the birth of species." Does it? It is not worth while posing opinion against opinion. Let us have some facts. Can the Duke of Argyll, or anyone else, adduce an observation of fact which necessarily leads to the conclusion that a given organ in a given animal or plant has passed through rudimentary stages in ancestral evolution in which that organ's rudiment had no use?

I am inclined to think that there are some cases which might appear to be of this nature, but are to be explained as due to "concomitant variation" or "correlation of growth" in a complex highly-elaborated organism, one part developing, though without use, as the necessary mechanical or structural condition of the development of another part which *has* use.

Such cases will not serve the purpose of establishing a general law. Will the Duke undertake to tell us what were the rudimentary stages of the limbs of Vertebrata in which actual use was impossible? Will he give a similar history of the vertebral column, or of the brain and spinal cord, or of the eye? In short, are there any facts in support of the theory of prophetic germs? Unless such facts are cited, your readers will conclude that the theory of prophetic germs is devoid of basis.

E. RAY LANKESTER.

45 Grove End Road, N.W., October 26.

Mr. Romanes's Paradox.

I SHOULD be sorry to have misrepresented the views of Mr. Romanes, especially on so formal an occasion as a Presidential address at a meeting of the British Association. But, if I have done so, I must plead in extenuation that I know of no recent writer whose papers I find so difficult to thoroughly comprehend. With an appearance of lucidity there seems to me to be often an

underlying obscurity of ideas by which I find myself as often completely befogged.

It appears to me that it is sometimes overlooked that what is usually called the "Darwinian theory" is set out in a book which bears as its title the words, not, as they are usually quoted, "The Origin of Species," but "The Origin of Species by Natural Selection." These words I regard as a proposition of which the book itself affords what is intended to be the proof. It seemed to me that Mr. Romanes intended to distinctly traverse this proposition, and, this being so, the careful consideration of his views became a matter of very great importance. Mr. Romanes now denies that he intended anything of the kind. But the denial comes rather late in the day, because the impression which I received from his paper at the Linnean Society was certainly shared at the time by others. For example, though it is unusual for a purely scientific paper to receive an extended notice in large print in the *Times*, Mr. Romanes was so favoured, and here is what the *Times* (August 16, 1886) says on one of the points on which Mr. Romanes complains that I have misrepresented him :—

"The position which Mr. Romanes takes up is the result of his perception, shared by many evolutionists, that the theory of natural selection is not really a theory of the origin of species, but rather a theory of the origin and cumulative development of adaptations." Now, I suppose Mr. Romanes would call this an "absurd misrepresentation." If so, it is singular that, as far as I remember, he took no steps to correct the statement of his views to which the *Times* gave its wide circulation.

But is it a misrepresentation? It is not, I think, difficult to cite a good deal of evidence that it is not. Anyone who will take the trouble to refer to the Journal of the Linnean Society, Zoology, vol. xix. p. 345, will find printed in capital letters across a page of Mr. Romanes's paper, "Natural Selection not a Theory of the Origin of Species." Now, everybody knows that the idea of the evolution of organic nature existed in men's minds long before Mr. Darwin. He did not originate it; what he did originate was the theory that "natural selection" is the mechanical means by which that evolution has been brought about. Mr. Romanes says roundly that it is not, or words have ceased to have meaning. Well, coming from "the biological investigator upon whom," the *Times* tells us, "in England, the mantle of Mr. Darwin has most conspicuously descended," I thought that a "startling paradox," and I said so. There was nothing very novel in this: it only put into other words what Mr. Wallace had already said (NATURE, vol. xxxiv. p. 467), when he took exception to Mr. Romanes's "extraordinary statement that, during his whole life, Darwin was mistaken in supposing his theory to be 'a theory of the origin of species,' and that all Darwinians who have believed it to be so have blindly fallen into the same error."

The next point on which Mr. Romanes complains is that I make him say specific differences are not adaptive, while those of genera are. And he calls this an absurd misrepresentation! It is really too comical, because it is the key of his whole strategic position. When Mr. Romanes read his paper at the Linnean Society, he began by saying that he regarded it as the most important work of his life. And the expression would certainly not have been exaggerated if he had succeeded in establishing what he terms (capitals again) the "inutility," *i.e.* non-adaptiveness, "of specific characters." Even Mr. Romanes could not assert that all specific characters are non-adaptive. But he asserts (NATURE, *l.c.*, p. 314) that "a very large proportion, if not the majority, of features which serve to distinguish species from species are features presenting no utilitarian significance." If this could be proved, it would be quite as effective as proving the proposition universally in inflicting a deadly blow on the Darwinian theory, the very essence of which is that specific differences must be advantageous. I agree with Mr. Wallace (NATURE, *l.c.*, p. 467) "that there is no proof worthy of the name that specific characters are frequently useless."

I am of course prepared to admit that, in regard to plants, about which only I feel competent to speak, there are a vast number of specific differences the adaptive significance of which we are either wholly ignorant of, or, at any rate, very imperfectly understand. But Mr. Darwin has himself led the way in a host of discoveries which have shown in innumerable directions, which had never been previously suspected, the adaptive significance of plant structures. We seem to me justified, then, in drawing the conclusion that all specific differences in plants are probably adaptive. This Mr. Romanes calls reasoning in a circle; to me it seems only a reasonable induction, the validity of which is strengthened every day by fresh observation.

As to the distinction which Mr. Romanes draws between specific and generic differences, I only summed up what he repeats again and again. Here is a specimen :—"It is comparatively seldom that we encounter any difficulty in perceiving the utilitarian significance of generic and family distinctions, while we still more rarely encounter any such difficulty in the case of ordinal and class distinctions. Why, then, should we encounter this difficulty in the case of specific distinctions?" In my opinion the actual state of things is exactly the reverse. But, as I discussed this point at some length in my Bath address, I need not touch upon it further.

I do not undertake to follow Mr. Romanes into all his dialectical subtleties. But the position which I understood him to have taken up in his paper was quite intelligible, and was of very great interest to the biologist. I briefly analyze it as follows :—Mr. Darwin explained the origin of species by natural selection; this implies that specific differences are adaptive; but this is not universally the case; it follows, then, that natural selection is not the explanation of the origin of species except when specific differences are adaptive, which, in point of fact, they are not in the majority of cases. It is clear that this shrivels up the part played by natural selection to very small dimensions, and minimises pretty effectively in proportion the position of the Darwinian theory in the field of biological speculation. The force, however, of the whole train of argument obviously depends, as I have remarked before, on the proof which can be given of the proposition that the majority of specific differences are non-adaptive. When we turn to the part of Mr. Romanes's paper dealing with this vital point, we only find some not very convincing assertions—some of which I think are erroneous—and no facts whatever. This is, however, not very surprising. Mr. Romanes is not a practised naturalist. His method is the very inverse of that of Mr. Darwin. We know that the latter for more than twenty years patiently accumulated facts, and then only reluctantly gave his conclusions to the world. Mr. Romanes, on the other hand, frames a theory which looks pretty enough on paper, and then, but not till then, looks about for facts to support it.

In my view, one is not called upon to give much attention at present to physiological selection. Still, a word or two may be devoted to it. The *Times* took an exception to the phrase of which I am surprised that Mr. Romanes has taken so far no notice. It says :—"How his theory can properly be termed one of selection he fails to make clear. If correct, it is a law or principle of operation rather than a process of selection." In point of fact, what Mr. Romanes calls physiological selection may be more accurately described as reproductive isolation. He supposes that individuals of a particular species arise which from some cause or other are incapable of breeding with other conspecific individuals. They are therefore in one aspect isolated, as if they were on an oceanic island. This being so, any casual variations which they exhibit will be perpetuated, he thinks, whether adaptive or not. And in this way he also thinks that species distinguished by non-adaptive characters have arisen. The idea is interesting, and Mr. Romanes believes that Mr. Darwin would have welcomed it. We know, however, that it occurred twelve years earlier to Mr. Belt, that Mr. Darwin was acquainted with it, and that "he did not regard it with any great favour." I myself have carefully considered it in connection with a variety of facts, and I have arrived at the conclusion that it is not a principle of very much value. It would take too long to set out the grounds for that conclusion here. But I may point out that such an isolated race would get no immunity from the general struggle for existence, while it would lose all the advantages to be obtained from free intercrossing. I am disposed to agree, then, with Mr. Wallace that, far from such races being "unable to escape the preserving agency of physiological selection," they would be very short-lived. Before leaving the subject, I cannot but remark on Mr. Romanes's singular choice of an alternative name for physiological selection—the "segregation of the fit." Segregation, I agree, is an improvement; but "fit" lets in the whole train of adaptive ideas, while Mr. Romanes insists that "the variations on the occurrence of which it [physiological selection] depends are variations of an unuseful kind."

One remark, and I shall conclude all that I propose to say about Mr. Romanes and his theory. What I introduced into my Bath address I had had long before in my mind. While I

was writing it, Prof. Huxley's obituary notice of Mr. Darwin came into my hands. I read it with the keenest pleasure, as everyone must; and I pointedly referred to it with a pardonable anxiety that a piece of work perhaps one of the most remarkable that ever came from that admirable literary workshop should attract a wider attention than from its mode of publication it might possibly receive. Personally, with regard to indifferent variations, I am a little disposed to think that Mr. Huxley is inclined to make too great concessions. I quite admit that correlated variation does give rise to a large class of non-significant characters. But I feel more and more that natural selection is a very hard taskmaster, and that it is down very sharply on structural details that cannot give an account of themselves. I doubt if there is much room in Nature for indifferent variations; and even correlated variations must be anchored, as it were, to an adaptive variation which has to bear the brunt of the maintenance of the whole correlated train.

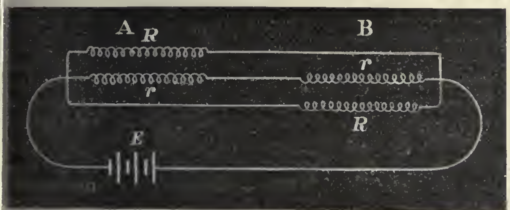
Royal Gardens, Kew, October 26.

Electro-Calorimetry.

In a paper read at the British Association meeting at Bath, Messrs. Stroud and Haldane Gee describe the method used by them for heating the liquids under experiment. Will you allow me to point out that the series arrangement of the coils is electrically in unstable equilibrium, since any difference of temperature between the baths causes less power to be spent in the cooler one, thus tending to increase the difference. With the coils in parallel less power is spent in the hotter bath, but the method is still imperfect from the want of equality of heating at different temperatures.

Coils may, however, be so arranged as to completely overcome these defects in an otherwise very simple and convenient apparatus. In the figure let A and B represent the two baths and the



coils therein, each bath being heated partly by a series coil of r_ω, partly by a parallel coil of R_ω. All four coils should be made of the same metal.

The necessary relation between R and r to secure equal heating may be found by writing $\frac{d \text{ watts in A}}{d\theta} = \frac{d \text{ watts in B}}{d\theta}$, where θ is the difference of temperature between the baths. When worked out this gives $R = 4r$; a result which is obviously true provided the coils have only a small temperature coefficient.

Sydney Evershed.

2 Victoria Mansions, S.W., October 10.

The "Tamarao" from Mindoro (Philippine Islands).

I have only just seen, in Nature of August 16 (p. 363), Dr. Sclater's communication of Prof. Steere's letter concerning the discovery of a new species of *Anoa* (*A. mindorensis*) in the Island of Mindoro. I beg to say that I forwarded a note on this imperfectly-known animal, whose native name is *Tamarao* (not "*Tamaron*," as far as I know), to the Zoological Society of London, and the note was printed in the Proceedings of the Society for 1878, pp. 881–82, under the title, "Letter concerning the supposed existence of the *Anoa* (*Anoa depressicornis*) in the Philippines." Since then, Dr. Hoffmann, formerly Assistant at the Royal Zoological Museum of Dresden, has published the results of his investigations on a skull of the *Tamarao*, which has belonged to the Dresden Museum since 1878, and which was brought by Prof. Semper from his travels in the Philippines (see *Abhandl. und Berichte d. k. Zool. und Anthr. Ethnogr. Museums zu Dresden*, 1886–87, No. 3, p. 26 *et seq.*, Plate 6, *a–f*). He proves, by a comparison of this skull with the skull of *Anoa* from Celebes, and with buffalo skulls from the Philippines and elsewhere, that this *Tamarao* has nothing to do with the genus *Anoa*, but is a true buffalo, viz. either *Bubalus indicus*, Rüt., or an undescribed variety of this species, or, perhaps, a new species of *Bubalus*. Between these alternatives we were unable to decide from the single skull in our hands, which, besides, is not that of a full-grown animal. If Prof. Steere be right in asserting that there exists a true *Anoa* in Mindoro, I can only conclude that the skull brought by Prof. Semper as that of the *Tamarao* of Mindoro, is not the true *Tamarao*.

R. Museum, Dresden, October 17. A. B. Meyer.

Pallas's Sand-Grouse (*Syrrhaptes paradoxus*).

It is obvious that this bird no longer appears to come much, if at all, under observation in Europe, although it was reported from almost every part during the months from April to June (see Meyer and Helm, *Orn. Jahresbericht der Beobachtungstationen im Königreich Sachsen*, iii. p. 117 *et seq*), and even later. I suppose nearly all the specimens have flown into the sea, and been drowned there. As regards its former appearances in Europe, a specimen of *Syrrhaptes paradoxus* is said to have been killed near Grenzdorf, in Silesia, about four years ago; and it is also said to have been observed near Sagan, in Silesia, in the years 1874–78; and in the year 1883 near Münster, in Westphalia. Whether these reports are authentic, I, of course, cannot say, the specimens not being in my hands.

R. Museum, Dresden, October 17. A. B. Meyer.

The Species of Comatulæ.

The writer of the notice of vol. xxvi. of the *Challenger* series, which appeared in Nature of October 11 (p. 561), remarks that the total number of living species of Comatulæ is given on p. 383 as 180, but that from the distribution list itself there would seem to be 188 species, and he adds that "possibly the seven additional species of Antedon and the one species of Actinometra named but not described may account for this discrepancy." If he will look at the list again he will find that though it contains the names of 8 MS. species, three of them belong to Actinometra and only five to Antedon. These, however, do not account for the apparent discrepancy, which is due to the fact that eight species are dimorphic, so that their names appear twice over, as is fully explained in the systematic tables on pp. 54, 58.

It will, of course, be understood that these lists only contain the names of such species as have yet been baptized, some few having received names before they could be described, on account of their serving as hosts to Myzostomida, which have been reported on by Prof. von Graff. But some time must unfortunately yet elapse before it becomes possible to make out a complete systematic and distribution list of all the Comatula-species which are still awaiting description in various Continental Museums. Some very interesting forms were obtained by the German ship *Gazelle* and by the Italian cruiser *Vettor Pisani*. Prof. Semper's Philippine collection, which contains several unusually fine individuals, is as yet undescribed, and I know of many other new types from various localities. At present, however, the fine collections made by the *Blake* in the Caribbean Sea during the years 1877–79 are occupying most of my little working time, and they well repay investigation.

Eton College, October 26. P. Herbert Carpenter.

Voracity of the Haddock.

A small haddock (*Gadus æglefinus*), alive when purchased on the fish quay this morning, was so much distended that curiosity prompted an investigation of the cause. In the stomach were found fourteen young whiting (*G. merlangus*) from 4 to 5 inches long, and a small crab (*Carcinus mænas*), with hard carapace, about 1 inch in diameter, all quite fresh, and digestion barely commencing. The haddock was 17 inches long, and weighed, when gutted, 26 ounces. The weight of the young fry and crab was 6½ ounces, or almost one quarter of the weight of the fish. Doubtless this record is often beaten in the deep, though the evidence of so healthy an appetite among fishes is not often so apparent. Chas. O. Trechmann.

Hartlepool, October 30.

The Queen's Jubilee Prize Essay of the Royal Botanic Society of London.

In your issue of October 18 appears (p. 594) a review of the essay for which I was awarded the medal of the Royal Botanic Society, in which the writer makes a great point of my omitting all reference to drugs. He does not state, for the information of your readers, that the prize was offered for the best (not necessarily complete) essay on the "Vegetable Substances introduced into Britain for use in the Arts, Manufactures, Food, and Domestic Economy during the Reign of Her Majesty Queen Victoria." It is not necessary that one should be either "a member of the medical profession" or have "a wholesome dread of drugs" to know that drugs used as medicines could not with any fitness be introduced into this essay; indeed, inquiry from the Secretary elicited the fact that they had been purposely excluded.

Had your reviewer read the essay with any care, he would have observed that I quote Dr. Forbes Watson to the effect that China grass and rhea fibre are products of the *same plant*, but prepared in different ways; while an unprejudiced reviewer would have mentioned that the quotation having reference to *Phormium tenax* is preceded in the essay by the words, "In one of the authorities consulted it is stated that New Zealand flax . . . was introduced into England about 1840; but the author has found a reference to an unsatisfactory attempt to weave it at Knaresborough at a much earlier period than this, and that it had been experimented upon in the Portsmouth Dockyard about 1819, the ropes made from it being satisfactory."

It was evident that the judges considered that "gun-cotton and its derivatives" *are* "direct products of the vegetable kingdom," or they would not have printed this chapter of the essay.

The limited time allowed for the preparation of the essay (about four months), and the inability of the author to avail himself of any collection of economic botany and of many of the most recent books on the subject, naturally led to many deficiencies in the list of substances mentioned, and of this no one was more conscious than the author himself; and all he claims for his essay is that, in the opinion of the judges (one of whom was Prof. Bentley), it was the best of the half-dozen sent in in competition.

John W. Ellis.

3 Brougham Terrace, Liverpool, October 23.

I have but few remarks to make in answer to Mr. Ellis's letter. First, I cannot follow his reasoning that completeness should not in some measure count as a test of quality, nor can I see anything in the preamble of the offer of the prize to exclude drugs. Mr. Ellis is justified, however, in having done so by receiving direct information from the Secretary to that effect.

On the subject of China grass and rhea, the author, in his essay, distinguishes them under separate heads, describing the first rightly as the produce of *Bœhmeria nivea*, and the second as "the produce of the East Indian *Bœhmeria* (*Urtica*) *tenacissima*, a congener of the species producing China grass." It is after this authoritative statement that he refers to Dr. Forbes Watson's opinion.

Regarding New Zealand flax (*Phormium tenax*), Mr. Ellis, in his essay, follows up the quotation given in his letter by the following paragraph: "Not having been introduced during the period to which this essay refers, any further mention of this interesting fibre—for which it has frequently been attempted to find a place in the British market—is unnecessary;" thus justifying my remarks on this head.

I leave it to anyone who has read Mr. Ellis's chapter on "Gun-cotton and its Derivatives," to say whether they are direct products of the vegetable kingdom.

The latter part of Mr. Ellis's letter, I think, supports the truth of my review generally.

The Reviewer.

October 27.

MODERN VIEWS OF ELECTRICITY.[1]

Part IV.—Radiation.

XII.

We must now mention one or two phenomena which depend entirely upon a modification of ether by the neighbourhood of matter, and which we have reason to believe would not occur in free ether at all. These are the optical phenomena of Faraday and Kerr, and the electric phenomenon of Hall.

Faraday discovered, long before there was any other connection known between electricity and light, that the plane in which light-vibrations occur could be rotated by transmitting light through certain magnetized substances along the lines of magnetic force. To make this effect easily manifest, one uses plane-polarized light and transmits it through a fair length of magnetized substance, analyzing it after emergence, and showing that, though it remains plane-polarized, the plane has been rotated, possibly through a right angle or more.

Now, in a general way it is easy to imagine that, inasmuch as something of the nature of a rotation is going on in a magnetic field round the lines of force, vibrations travelling into such a field along these lines should be twisted round, corkscrew fashion, and emerge vibrating in a different plane. But when one tries to follow out this process into detail, one finds it not quite so simple a matter. It has no business to be a very simple and obvious consequence of the existence of a magnetic rotation round the rays of light, else would it occur in free space, and in the same direction in all media. But the facts are that in free space—that is, in free ether—it does not occur at all, and the direction of rotation is not the same for all media: substances can, in fact, be divided into two groups, according to the way in which given magnetization shall rotate the plane of polarized light passing through them.

Similarly with the electrostatic optical effect discovered by Dr. Kerr, who showed that plane-polarized light transmitted across the lines of force in an electrostatic field could, in certain media, come out elliptically polarized. Now, inasmuch as an electric field is a region of strain, and strain in transparent bodies is well known to make them slightly doubly refracting and able to turn plane-polarized into elliptically-polarized light, it is very easy to imagine such a result in an electric field to be natural and probable. But the explanation is not so simple as that, else it ought to be a large effect, occurring in all sorts of media in the same direction, and likewise in free space. But the facts are that it does not occur at all in free space, and it occurs in different senses in different substances; so that again they can be grouped into two classes according to the sign of the Kerr effect.

Thus, then, the rotatory effect of a magnetic field upon light, discovered by Faraday, and the doubly refracting effect of an electrostatic field upon light, discovered by Kerr, agree in this: that they are both small or residual effects, depending on the existence of a dense medium, and both varying in sign according to the nature of the medium.

The only substance in which the Faraday effect is large is iron, including with iron the other highly magnetic substances. The discovery of the effect in these bodies was likewise made by Kerr. The difficulty of dealing with them is that they are very opaque, and hence that the merest film of them can be used. The film can be used either by way of transmission or by way of reflection, it matters not which, but reflection is perhaps the more convenient. Light reflected from the pole of a magnet has indeed barely penetrated at all into the substance of the iron before being sent back; still, it has penetrated deep enough to be distinctly rotated by the tremendous magnetic whirl which it finds there. All these highly magnetic substances are metallic conductors, and are therefore very opaque.

Whether there is any real connection between high magnetic susceptibility and conductivity is more than I can say. But it is quite natural, and indeed necessary, that the greatest portion of light should be reflected on entering a highly magnetic medium, because in such a medium the ethereal density, μ, is so great, and hence the

[1] Continued from vol. xxxviii. p 592.

velocity of wave transmission must undergo a sudden and immense decrease—a circumstance always causing a great amount of reflection, just as when sound tries to pass from any one medium to a much denser one.

But the opacity of iron and other magnetic substances may be explained by the mere fact of their conducting power, just like other metals, and no noteworthy effect of their large value of μ need be detectable.

If a non-conducting highly magnetic substance could be found, it would probably reflect a great deal of light at its surface, though it would not dissipate that which entered it. Such a substance would be most interesting to submit to experiment, but perhaps its existence presupposes a combination of impossible properties.

As to the phenomenon detected by Hall, it appears intimately associated with that of Faraday, and it will be most simple to omit all reference to it for the present.

A general idea of what is happening in the Faraday and Kerr phenomena can be given thus. A simple vibration, like a pendulum-swing, or any other oscillation in one plane, can be resolved into two others in an infinite variety of ways; just as one force can be resolved into any number of pairs of equivalent forces. The two most useful modes of analyzing a simple vibration into a pair of constituents are these: (1) two equal components, likewise plane vibrations, each inclined at 45° to the original one, as when P Q is resolved into A B and C D (Fig. 49); and (2) two equal circular or rotatory oscillations in opposite directions,

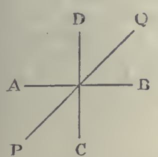


Fig. 49.

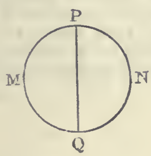

Fig. 50.

as when P Q is resolved into P M Q and P N Q (Fig. 50). The first method of resolution is useful in explaining Kerr's effect, the second in explaining Faraday's.

Of the two component vibrations, A B and C D, into which P Q can be supposed analyzed, let some cause, no matter what, make one gain upon the other, so that in travelling along a line perpendicular to the paper one goes a little the quicker: the effect at once is to change the character of the vibration into which they will recompound. After the gain, they no longer reproduce the original simple vibration P Q: they give rise to elliptic, or it may be to circular, vibrations; this last, if the retardation is equal to a quarter period.

These are matters fully treated in any elementary treatise on polarized light, and they are quite easily illustrated by means of a simple pendulum. One may assume them known.

Similarly with the second system of analyzing the vibration into two opposing circular ones. If the components travel through any interposed medium at the same rate, they will, on emergence, reproduce the original vibration in its original position; but if one travels quicker than the other they recombine into a vibration of the same character as at first, but turned through a certain angle. Thus anything which retards one of the *rectangular* components behind the other changes the character of the vibration from plane into elliptical; while anything which retards one of the *circular* components behind the other leaves the character of the vibration unaltered, but rotates it through a certain angle.

So far one has said nothing but the simplest mechanics. The next point to consider is what determines the rate at which light travels through any substance? This we have discussed at length, and shown to be $\frac{1}{\sqrt{(K\mu)}}$. Anything which increases either the electric or the magnetic permeability of the medium decreases the velocity of light. Now, when a medium is already subject to a violent strain in any one direction it is possibly less susceptible to further strain in that direction and responds less readily. Not necessarily so at all: such an effect would only be produced when the strain was excessive, when the medium was beginning to be overdone, and when its properties began thereby to be slightly modified. There are reasons for believing the specific inductive capacity of most media to be very constant; of some media, perhaps, precisely constant; but if there were any limit beyond which the strain could not pass it is probable that on nearing that limit the specific inductive capacity would be altered—possibly increased, possibly diminished—one could hardly say which. Quincke has investigated this matter, and has shown that the value of K is affected by great electric strain.

Suppose now that a dielectric is subject to a violent electrical stress, so that its properties along the lines of force become slightly different from its properties at right angles to those lines. The value of K will not be quite the same along the lines of strain as across them, and accordingly the rectangular component of a vibration resolved along the lines of force will travel rather quicker or rather slower than the component at right angles, because the velocity of transmission depends upon K as already explained: such a medium at once acquires the necessary doubly-refractive character, and will show Kerr's effect.

Similarly with magnetization. It is well known that for many media μ is not constant. Take iron, for instance. For very small magnetizing forces the susceptibility is moderate, and increases as they increase; at a certain magnetization it reaches a maximum, and then steadily decreases. But not only is it thus very inconstant, its ascending and descending values are not the same. To forces tending to magnetize it more, the susceptibility has one value; to forces tending to demagnetize it, it has another and in general smaller value. This property has been specially studied by Ewing, and has been called by him "hysterĕsis." Slightly susceptible substances cannot be magnetized to anything like the same extent, and hence the property in them has been less noticed, perhaps not noticed at all. Nevertheless it must exist in every substance which exhibits a trace of permanent magnetism, and every substance I have tried appears to show some such trace (see NATURE, vol. xxxiii. p. 484).

An already strongly magnetized medium will be rather differently susceptible to additional magnetizing forces in the same direction than to those in a contrary direction. Nothing more is wanted to explain Faraday's effect. The vibration being resolved into two opposite circular components, one of them must agree in direction with the magnetism already in the medium and try to magnetize it for the instant infinitesimally more; the other component will for the instant infinitesimally tend to demagnetize it. The value of μ offering itself to the two components will be different, hence they will go at different rates, and the plane of vibration will be rotated.

The direction of rotation will depend on whether the value of μ is greater for small relaxations or for small intensifications of magnetizing force; and diamagnetic substances may be expected to be opposite in this respect to paramagnetic ones. Any substance for which μ is absolutely constant, whatever the strength of magnetic polarization to which it is submitted, can hardly be expected to exhibit any hysterĕsis; the ascending and descending curves of magnetization will coincide, being both straight lines, and such a substance will show no Faraday effect. Similarly, any substance for which K is absolutely constant, whatever the electric polarization to

which it is submitted, can show no Kerr's effect. Free space appears to be of this nature; and gases approach it very nearly, but not quite.

In iron, μ is greater for an increasing than for a decreasing force, as is shown by the loops in Ewing's curves; hence the circular component agreeing in direction with the magnetizing current will travel slower than the other component, and hence the rotation in iron will be against the direction of the magnetizing current. The same appears to hold in most paramagnetic substances, and the opposite in most diamagnetic, but the mere fact of paramagnetism or diamagnetism is not sufficient to tell us the sign of the effect in any given substance. We must know the mode in which its magnetic permeability is affected by waxing and by waning magnetization respectively.

Possible Electrical Method of detecting the Faraday Effect.

Thus far we have considered the rotation of electric displacement by a magnetic field as being examined optically, the displacements being those concerned in light, and the rotation being detected by a polarizing analyzer suitable for determining the direction in which the vibrations occur before and after the passage of light through a magnetized substance. This is the only way in which the effect has at present been observed in transparent bodies. But one ought not to be limited to an optical method of detection.

Electrical displacements are easily produced in any insulator, and if it be immersed in a strong magnetic field so that the electric and magnetic lines of force are at right angles to each other, every electric disturbance ought to experience a small rotation. A steady strain will not be affected; it is the variable state only which will experience an effect, but every fresh electric displacement should experience a slight rotatory tendency just like the displacements which occur in light.

Now to rotate a displacement A B into the position A C requires the combination with it of a perpendicular displacement B C (Fig. 51). Hence the effect of the magnetic

FIG. 51.

field upon an electric displacement, A B, may be said to be the generation of a small perpendicular E.M.F., B C, which, compounded with the original one, has the resultant effect A C. It will be only a temporary effect, lasting while the displacement is being produced, and ceasing directly a steady state of strain is set up.

An inverse E.M.F., A D, will be excited by the same magnetic field directly the displacement is reversed.

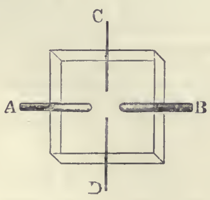

FIG. 52.

And so, if a continual electric oscillation is kept up between A and B in a magnetic field, an accompanying very minute transverse oscillation may be expected, and may be looked for electrically.

Some such arrangement as that here shown (Fig. 52) may be employed. A square of heavy glass, perforated with four holes towards the centre, supplied with electrodes; one pair of electrodes, A, B, to be connected with the poles of some alternating machine, and the other pair, C, D, connected to a telephone or other detector of minute oscillatory disturbance. So soon as a strong steady magnetic field is applied, by placing the glass slab between the poles of a strong magnet, the telephone ought to be slightly affected by the transverse oscillations. This effect has not yet been experimentally observed, but it seems to me a certain consequence of the Faraday rotation of the plane of polarization of light.

Hall Effect.

Although the existence of this transverse E.M.F., excited by a magnetic field in substances undergoing varying electric displacement, has at present only been detected optically in transparent bodies, *i.e.* in insulators, yet in conductors the corresponding effect with a steady current has been distinctly observed electrically. By many persons it had been looked for (by the writer and Prof. Carey Foster, among others, though unfortunately they were not sufficiently prepared for its extreme smallness); by Mr. Hall, at Baltimore, was it first successfully observed.

In conductors it is natural to use a conduction-current instead of a displacement-current. A steady current can be maintained in a square or cross of gold-leaf or other thin sheet of metal between the electrodes A, B, and a minute transverse E.M.F. can be detected, causing a very weak steady current through a galvanometer connected to the terminals C, D, so soon as a strong magnetic field is applied perpendicularly to the plate. Fig. 53 will

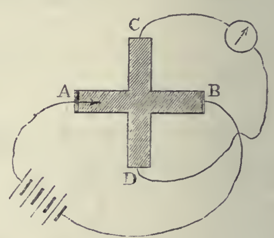

FIG. 53.—The direction of the transverse E.M.F. excited by the earth's vertical magnetic field in this conductor, conveying a current as shown, is C D if it represents gold, D C if it represents iron.

sufficiently indicate the arrangement. The poles of the magnet are one above and one below the paper.

In iron it is easy to see which way the transverse E.M.F. ought to be found. It has been shown that a displacement will be rotated in iron against the magnetizing current; hence, to rotate the displacement A B to A C (Fig. 51), requires in iron a clockwise magnetizing current. Such a current, or, what is the same thing, a south pole below the paper, a north pole above, excites, in the cross of Fig. 53, E.M.F. in the direction D C, and this by Ampère's rule is just the direction in which the conductor itself is urged by the magnetic forces acting on the current-conveying substance. Most diamagnetic substances should exhibit a transverse E.M.F. in the opposite sense. This transverse E.M.F. excited in conductors conveying a current in a magnetic field is the effect known by the name of Hall. It is, as Prof. Rowland and others have pointed out, intimately connected with the Faraday rotation of light.

Unfortunately a pure and simple Hall effect is a difficult thing to observe. Magnetism affects the conductivity of metals in a rather complicated manner, and strain affects their thermo-electric properties. Now, a metal

conveying a current in a magnetic field is certainly more or less strained by mechanical forces, and hence heat will be developed unequally in different parts, by a sort of Peltier effect; and the result of this will be to modify the resistance in patches and so to produce a disturbance of the flow which may easily result partly in a transverse E.M.F. This has been pointed out by Mr. Shelford Bidwell.

The more direct effect of magnetism on conductivity may be negligibly small in many metals, but in bismuth it is certainly large. Both of these spurious effects seem to be large in bismuth, and probably quite mask any true Hall effect there may be in that metal. In all cases the existence of these spurious effects makes it difficult to be sure of the magnitude and sign of the real rotational effect.

But, it may be asked, what right have we to distinguish between a real and a spurious Hall effect? If a transverse E.M.F. can be predicted by reason of known strains and thermo-electric properties, as well as by known rotation of light effects, why should the two things be considered different? Why should they not be different modes of regarding one and the same phenomenon?

In other words, may not the Faraday rotation of light vibration be due to infinitesimal temporary strains and heatings in the medium caused by the fact that minute electric displacements are occurring in a violent magnetic field? This is a question capable of being answered by a quantitative determination of the amounts and direction of the effects to be expected, and a comparison with those actually observed. I do not know of data at present obtained sufficient to enable us to answer it. If the answer should turn out to be in the affirmative, the phenomenon of hysteresis will be at once linked, by an underground path, with those of thermo-electricity and strain.[1]

OLIVER J. LODGE.

(*To be continued.*)

[1] Perhaps I ought to caution students not to accept my connection of Faraday's or Hall's effect with hysteresis as in any way authoritative. Until these views have been criticized it will be wise to place no reliance on them.

IRREGULAR STAR CLUSTERS.

IT is not always easy to distinguish between a casual "sprinkle" of stars and a genuine cluster. The movement-test, by which so many physical have been discriminated from optical double stars, is here inapplicable. The Pleiades are the only considerable group possessing an ascertained common proper motion. All other clusters, debarred as yet from the appeal to this demonstrative argument of their physical nature, have to depend solely upon evidence from probability, with its indefinite variations of conclusiveness according to the circumstances of each particular case. It is, however, in general, amply sufficient. Among five hundred clusters registered as such, there are few indeed as to which there can be any doubt of their forming separate systems; although many real aggregations may exist unrecognized, owing to their loosely scattered character.

Two inferences may be safely derived from the results of recent inquiries into the constitution of the Pleiades. First, that interstitial movements in clusters are likely to be so extremely slow that centuries must elapse before they can become conspicuous; next, that stars showing somewhat marked displacements are presumably mere travellers across, and no genuine components of, the cluster they seem to belong to. An example of this kind of temporary association is almost certainly furnished by an apparent member of a scattered group in Ophiuchus ("Gen. Cat." 1440), the position of which was found, by the comparison of photographs taken by M. von Gothard in 1886 with Vogel's measures of eighteen years previously, to have changed to the extent of 45″, or at the rate of 2½″ annually (*Astr. Nach.*, No. 2777). Its motion, if rectilinear, would carry it from end to end of the collection it is projected upon, in 360 years; and its eventual detachment from it may have become palpably inevitable within ten. The star is of the eleventh magnitude, and is by far the swiftest-moving yet known of so small a size.

Several of the stellar gems surrounding κ Crucis are suspected of considerable mobility. Sir John Herschel, during his visit to the Cape, determined the relative places of 110, all included in an area of about $\frac{1}{48}$ of a square degree ("Cape Observations," p. 17); and the process was, by Mr. H. C. Russell, of Sydney, in 1872, repeated and extended to 130 components (*Monthly Notices*, vol. xxxiii. p. 66). The result was to bring out discrepancies which, if really due to movements of the grouped stars, would be of extreme interest. Herschel's measurements, however, were necessarily too hasty to be minutely reliable; so that changes depending upon their authority need to be confirmed by continuance before they can be unreservedly accepted. The same qualification applies to M. Cruls's discovery of orbital revolution in three double stars within the precincts of the cluster (*Comptes rendus*, t. lxxxix. p. 435).

The stars about κ Crucis are famous for the loveliness of their varied hues. Blue and green, red and sulphur-coloured orbs shine together in a matchless sidereal picture, setting at the same time a problem in sidereal chromatics by no means easy to solve. There is no evidence of change of tint among them since Herschel's time, but there is some, tolerably conclusive, as to change of brightness.

Many irregular clusters seem to be throughout made up of star-streams and reticulations exactly similar to the inflected appendages of globular clusters. A collection (M 24) visible to the naked eye as a dim cloudlet near μ Sagittarii, and regarded by Sir John Herschel as intimately connected with, if not an actual part of, the Milky Way, was named by Father Secchi "Delle Caustiche," from the peculiar arrangement of its stars in rays, arches, caustic curves, and intertwined spirals. Closely adjacent to it, he noted a group of eleventh magnitude stars forming three spokes, as it were, and the nave of a wheel, the axis of which was occupied by a much brighter close pair (*Atti dell' Accad. Pont.*, t. vii. p. 72).

The same kind of radiated structure is apparent in a stellar swarm near the right foot of Castor (M 35), which, with Lassell's 24-inch mirror, showed as so "marvellously striking an object that no one could see it for the first time without an exclamation." A field 19′ in diameter "is perfectly full of brilliant stars, unusually equal in magnitude and distribution over the whole area. Nothing but a sight of the object itself can convey an adequate idea of its exquisite beauty" (*Monthly Notices*, vol. xiv. p. 76). Admiral Smyth described it as "a gorgeous field of stars from the ninth to the sixteenth magnitudes, but with the centre of the mass less rich than the rest. From the small stars being inclined to form curves of three or four, and often with a large one at the root of the curve, it somewhat reminds one of the bursting of a sky-rocket" ("Cycle of Celestial Objects," p. 168, Chambers). A marvellously perfect photograph of this cluster, taken by the MM. Henry, March 10, 1886, exhibits not less than two thousand stars disposed in a roughly-indicated, eight-rayed figure, the branches often connected by drooping chains, and composed in detail of sinuous lines, or "fantastically crossing arcs" of stars (Secchi, *loc. cit.*).

About one hundred connected stars in Ophiuchus ("G. C." 4346) "run in lines and arches" (J. Herschel, Phil. Trans., vol. cxxiii. p. 460); a collection of eleventh magnitude ones in Sagittarius ("G. C." 4323) are scattered along "zigzag lines." The constituents of a large cluster near the Poop of Argo ("G. C." 1649) struck the elder

Herschel by their arrangement "chiefly in rows," by which he gained some insight into the mechanical complexities of such systems. Each row, he observed, while possessing its own centre of attraction, will at the same time attract all the others; nay, "there must be somewhere in all the rows together the seat of a preponderating clustering power which will act upon all the stars in the neighbourhood" (Phil. Trans., vol. civ. p. 269). Speculations, indeed, upon the dynamical relations of "stars in rows," are still premature; nor are they likely, for some time to come, to be accounted as "of the order of the day." But the continual recurrence in the heavens of this mode of stellar aggregation cannot fail to suggest the development of plans of systemic dissolution and recomposition on too grand a scale to be other than vaguely apprehended by us.

The more attentively clusters are studied, the more intricate their construction appears to be. That which challenged Herschel's notice is not singular in exhibiting the federative union of a number of subordinate groups. There is rarely evidence, in the conformation of irregular clusters, of their being governed from a single focus of attraction; there are frequent indications of the simultaneous ascendancy of several. A cluster in Sagittarius ("G. C." 4335) is distinctly bifid. It was remarked by Sir John Herschel at Feldhausen as "divided by a broad, vacant, straight band" ("Cape Observations," p. 116). The fission (as in many nebulæ), no longer in the inchoate state of a "dark lane," is complete. Admiral Smyth's stellar "flight of wild ducks," in Sobieski's Shield (M 11), is perhaps trifid. Father Secchi, at least, perceived in it a three-lobed central vacuity (*Atti dell' Accad. Pont.*, t. vii. p. 75). Sir John Herschel, on the other hand, succeeded by the use of high powers, in breaking up "this glorious object" "into five or six distinct groups with rifts or cracks between them" (Phil. Trans., vol. cxxiii. p. 462). M. Helmert's measures of two hundred of its components referred to a ninth magnitude star conspicuous among them ("Publicationen der Hamburger Sternwarte," No. 1, 1874) will eventually afford the means of detecting their relative displacements. Several of them appear to be variable.

The disruptive tendency indicated by the peculiarities of their distribution is equally marked in "a reticulated mass of small stars" in Cygnus ("G. C." 4511), described at Parsonstown as "a most gorgeous cluster, *full of holes*." The figure published by Lord Rosse shows a winding ribbon of stars inclosing three blank circular spaces, of symmetrically diminishing diameters.

Star-groupings of curiously definite forms are often met with. A triangular swarm ("G. C." 5055) occurs in the tail of Cetus; a rectangular area in Vulpecula ("G. C." 4498) is densely strewn with fine star-dust. Clusters shaped like open fans are tolerably numerous. One situated in Gemini would appear, according to Sir John Herschel, if removed to a sufficient distance, "as a fan-shaped nebula with a bright point like a star at the vertex." Another specimen of an "acutangular" cluster ("G. C." 4902) is bounded by "two principal lines of stars drawing to one" (Phil. Trans., vol. cxxiii. pp. 476, 503). It is 2′ in length, and is to be found in the constellation Cepheus. An oval annulus of stars in Cygnus, 4′ across ("G. C." 4701), centrally surrounds a ruddy ninth magnitude star. A similar elliptical group, with a double substituted for the red star, constitutes a quasi-nucleus for the great cluster in Perseus ("G. C." 512). This superb object, like the still richer group it immediately precedes, has probably galactic affinities. The two together form a telescopic pageant such as, in the wildest flights of imagination, Hipparchus could little have dreamed would one day be unrolled before the eyes of men, out of the "cloudy spot" in the sword-handle of Perseus which he was the first (it is said) to detect. Although the outliers of the two clusters can be brought within the same field of view, they are believed to be really disconnected. The following, and more considerable (known as χ Persei) was micrometrically investigated by Vogel in 1867–70, photographically by O. Lohse in 1884 (*Astr. Nach.*, No. 2650). The result of the comparison of 172 stars was to show their complete immobility in an interval certainly too short for the visible development of such tardy movements as were alone likely to be in progress. A rapid spectroscopic survey executed by Vogel with the Berlin 9-inch refractor, March 30, 1876 ("Der Sternhaufen χ Persei," p. 31), disclosed nothing remarkable in the light of any of the clustered stars, although several of them have been called red, "pale garnet," and even "ruby." Their comparative brilliancy suggests that this magnificent assemblage, as well as its neighbour, may be less exorbitantly distant from the earth than most other objects of its class.

Red and double stars often—we are at a loss to imagine for what reason—seem to dominate in clusters. Compound objects must of course, through the chances of optical juxtaposition, occur most freely where stars are most crowded; yet when they are marked out (as often happens) both by superiority of lustre and by distinction of place, some significance may be attached to their presence. Thus, each of the oblique arms of a "cruciform" group in Auriga ("G. C." 1119), photographed at Paris on January 28, 1887, carries a pair of conjoined stars brighter than the rest (Smyth, "Cycle," p. 140). A "superb cluster" in Monoceros ("G. C." 1637), standing on a background of sky "singularly dotted over with infinitely minute points," has a double star in its most compressed part (J. Herschel, Phil. Trans., vol. cxxiii. p. 386). The central star in Præsepe is double; and there are many examples of more restricted groups gathered round a compound luminary.

Groups apparently ruled by a conspicuous ruddy star are met with in the constellations of the Swan ("G. C." 4676) and Auriga ("G. C." 1067). Another in Cygnus ("G. C." 4701) has already been mentioned.

The nebular affinities of stellar swarms are full of interest, but have as yet been very imperfectly investigated. The discoveries in the Pleiades, however, which may not prove to be the only cluster involved in cosmical fog-wreaths, show what can be done in this direction by the aid of photography. But since nebulæ thus situated are likely to be of the last degree of faintness, the stars probably replacing their original more brilliant knots, their existence can scarcely be made manifest otherwise than by prolonged exposures of plates of the highest sensitiveness. Visual detections of the kind will always be rare. Two rich clusters have nevertheless long been known to include each a nebula of the planetary kind. One in Argo ("G. C." 1801) has a central vacuity conspicuously occupied by a nebulous disk 40″ across; the other (M 46), not far from the head of Canis Major, displays well within its borders a fine annular nebula ("G. C." 1565). It is difficult, if not impossible, to believe either projected casually into such a very remarkable position.

The occurrence of *clusters within clusters* can just as little be set down to the account of chance. In one such instance, a large loose collection in Gemini ("G. C." 1490) involves a neat group of "six or seven stars close together, and well isolated from the rest" (Lord Rosse, Trans. R. Dublin Soc., vol. ii. p. 56). The companion example ("G. C." 1383) is found in the Milky Way, near Orion's right arm.

Researches into the mutual relations of clustered stars are still in their infancy. They will demand for their prosecution a reserve of patience as inexhaustible as the store of problems to be successively confronted. Before these come to an end, the human race itself will perhaps have become terrestrially extinct. But not, we may hope, before much has been attained that is well worth waiting and working for.

A. M. CLERKE.

THE COLOURING MATTER OF THE TESTA OF THE SEED OF RAPE (BRASSICA NAPUS).

THE testa of the seed of this species of Brassica is dark brown in colour, so dark often as to appear almost black. Being curious as to the chemical nature of the colour in this outer seed skin, I made several very simple experiments (which, however, have been thoroughly successful) with a view to elucidate the matter. After trying many solvents I was able to dissolve out the greater part of the colouring material by the use of that very common solvent, viz. a 25 per cent. solution of hydrochloric acid.

I put two or three hundreds of rape-seeds into a large test-tube (boiling-tube), covered them over completely with the dilute hydrochloric acid, and let the whole stand for three days.[1]

At the end of that time the solvent had acquired a very distinct pale brownish-violet (inclining to magenta) colour.

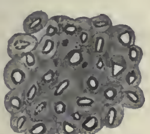
When a little of this dilute hydrochloric acid extract was mixed with as much *strong pure* hydrochloric acid, and gently heated, an intense yellow colour was developed, pointing to the very probable presence in the solution of iron in the ferric condition.

When potassium ferrocyanide was added to another portion, in a test-tube, of the original dilute HCl solution, a pale greenish-blue colour, which gradually darkened, was produced, and, after standing for about a day, the characteristic Prussian-blue precipitate indicative of ferric iron was observed to have settled to the bottom of the tube.

Potassium sulphocyanide confirmed the results obtained above, by giving, when added to the original solution, a well-marked blood-red coloration, showing the certain presence of a ferric compound in the liquid tested.

By these simple experiments I proved the presence of iron. I now wished to ascertain the nature of the iron compound in the testa which gave it its characteristic colour. I adopted the following simple method of investigation:—

I soaked for about a day a hundred or so of seeds. Then I took off the skins, which the soaking had rendered easily removable, placed them on a clean platinum foil, and heated to and kept at a white heat till all the water and organic matters were driven off, and nothing but ash remained. This ash—which was very small in quantity, of course—was reddish-brown in colour, and so was *undoubtedly*, in large measure at least, ferric oxide. When this red ash was treated with moderately strong hydrochloric acid, the intense yellow colour due to the production of ferric chloride was developed, and the potassium ferrocyanide and the sulphocyanide give the characteristic tests recorded above.



Section of testa of rape-seed showing thick corky cell-walls impregnated with hydrated (?) ferric oxide. (× 160).

No doubt, then, was left in my mind by these experiments that the iron existed in the state of ferric oxide (most probably hydrated ferric oxide or limonite) in the testa of the rape-seed. I was next anxious to know how the ferric oxide was distributed in the corky tissue of the testa. It soon occurred to me that this was also a very simple matter to investigate. I embedded several testas in paraffin, and by means of my microtome cut several thin sections, mounted in water, and examined them with a medium microscopic power. The cell-cavities were entirely empty; the thick corky walls were quite red. There, then, in the walls, plainly enough, the ferric oxide was seen to be distributed.

How did the ferric oxide get into its place in these walls? This, I think, is the explanation. The iron was taken in from the soil, by the root hairs of the plant which produced the seeds, chiefly in the ferrous state, probably as ferrous carbonate or chloride. It was conveyed in the water stream through the parent plant to the seed, and there deposited as an accessory substance in the cell-walls of the testa amongst the corky matter while the process of wall-thickening was going on. It was afterwards, or during the process of deposition, oxidized and hydrated (?), and so the seed of *Brassica Napus* acquired its characteristic tough dark brown testa.

ALEXANDER JOHNSTONE.

Edinburgh University.

[1] I know now that it was not necessary to let the seeds remain in the acid so long. By a little gentle and judicious heating for about twenty minutes sufficient of the colouring substance would be extracted to enable one to determine its nature.

THE TAIL-BRISTLES OF A WEST INDIAN EARTHWORM.

I HAVE recently received from Mr. Reginald Windle a small collection of earthworms from Bermuda, among which is a new species showing a remarkable peculiarity of structure which I have not observed, or seen recorded, in any other earthworm.

The posterior extremity, for the length of about half an inch (the worm measures about three inches), is furnished with bristles, which, as in *Urochæta*, are disposed in an alternate fashion; the eight bristles on each segment do not correspond in position to those of the preceding or succeeding segments, but are placed so as to correspond to the intervals between them.

In my specimen the bristles at the end of the body were extremely conspicuous, and, when examined by a lens, appeared to end in a thickened head; the skin felt sticky when touched by the finger. When a portion of the body-wall was teased up in glycerine, and examined with a microscope, the bristles showed the very remarkable shape indicated in the accompanying woodcut (Fig. 1, *a*). The bristle is very large—compared with those upon the more anterior segments (*b*) and those of other

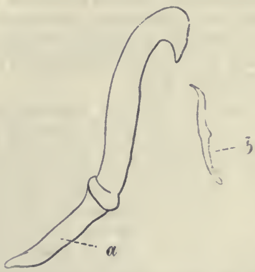


FIG. 1.—*a*, one of posterior setæ; *b*, seta from about middle of body. Both drawn to scale with *camera lucida*.

earthworms—and the free end is bent into a hook, the point of which lies in a direction nearly parallel to that of the shaft. The whole bristle is enormously thicker than those which are found upon the anterior segments, and of a deep yellow colour. At about the middle of the shaft, where a slight swelling is commonly met with in the bristles of other earthworms, is a thickened rim which suggests the attachment of powerful muscles. The hooked end of the bristles accounts for the "sticky" feeling of

the skin, which I was first inclined to ascribe to a secretion of the cutaneous glands.

This curious modification of the posterior bristles has an evident relation to the habits of these creatures. All observers, from the time of Gilbert White onwards, have noticed that earthworms constantly, at night and in wet weather, lie outside their burrows with only the extreme end of the body fixed in the hole; when alarmed they dart back with great rapidity. Now it is quite clear that this movement depends upon the fact that the bristles at the posterior end hold that part of the body firm while the anterior part is being retracted. Probably the alternate arrangement of the bristles in *Urochæta* and in the Bermuda worm (which is a close ally of *Urochæta*, if not a species of the same genus) are useful to the worm in performing such rapid movements, inasmuch as they permit of a firmer hold of the ground. When these bristles become strong hooks, as in the Bermuda worm, the stability of the hinder end of the body must be enormously increased.

I have, however, no information as to the habits of these worms, so that I can only suggest a possible explanation of the presence of these remarkable hooks.

FRANK E. BEDDARD.

NOTES.

OUR readers will be glad to hear of the safety of Prof. A. C. Haddon, of the Royal College of Science, Dublin, who recently started for Torres Straits. He writes, under date September 9, reporting himself in good health, and well pleased with both the climate and his reception. If he is carrying out his original programme, he should be now busy among the islands in the middle of the Great Barrier Reef to the west side of the straits. His captures already embrace several new Actiniæ and some probably new Nudibranchs; and he is also at work upon the habits and placentation of the Dugong. He is much interested in the natives, and struck by the alarming rapidity of their decrease and modification. They are fast dying out, and their customs with them, and the information to be obtained from the younger men concerning the doings of their forefathers is so unsatisfactory that Prof. Haddon is losing no opportunity of studying the anthropology of the islanders and of collecting material in illustration thereof.

IT is understood that Prof. Giard is about to be appointed immediately to the new Professorship of Évolution des Êtres Organisés in the Sorbonne. His lectures will begin this month, and the first course will deal with embryological phenomena in relation to the Darwinian theory.

La Nature (October 20) prints an interesting article, by Dr. Camille Viguier, on the Zoological Station at the town of Algiers, the only institution of the kind which has yet been established on the southern coast of the Mediterranean. Eight years ago, when schools of law, science, and literature were formed at Algiers, Dr. Viguier resigned an educational office he held in France, in order to associate himself with the new Algerian schools, in the hope that he might be permitted to create a marine laboratory. This hope has been fulfilled, and, although the site has some disadvantages, he is, upon the whole, satisfied with the opportunities of research which have been provided for him. He calls especial attention to the fact that it is not necessary for naturalists to go to Algiers to profit by the institution. Those who write to him will receive, as soon as circumstances permit, and prepared in accordance with their directions, any animals that can be procured at Algiers.

THE Trustees of the British Museum have appointed Mr. Alfred Barton Rendle, late Assistant Demonstrator of Botany, Cambridge, an assistant in the Department of Botany at the Natural History Museum, in the vacancy occasioned by Mr. H. N. Ridley's taking the office of Director of the Botanical Gardens at Singapore.

MR. H. BURY, who has recently been elected to a Natural Science Fellowship at Trinity College, Cambridge, began the study of biology at Eton, and obtained a First Class in the Natural Science Tripos of 1885 (Part I.), having previously gained a Foundation Scholarship at Trinity College. He spent the winter of 1886–87 at the Naples Zoological Station, and the results of his work, which has added much to our knowledge of the development of Comatula, have been recently published in the Philosophical Transactions, with five illustrative plates. He returned to Naples at the beginning of the present year to study the larvæ of other Echinoderms, and his observations will be published in an early number of the *Quarterly Journal of Microscopical Science*.

THE Princess Louise will open the Durham College of Science, Newcastle, on Monday next, November 5, at 12 o'clock.

IT is reported from India that Mr. Griesbach, the geologist of the Indian Survey, sent for a time to Afghanistan at the request of the Ameer, has been compelled by the rebellion of Ishak Khan to postpone his geological exploration north of the Hindu Kush, and to remain at Cabul.

ACCORDING to *Allen's Indian Mail*, it is the intention of the Government of India to utilize the services of Mr. J. Duthie. Hitherto that gentleman has confined his botanical researches to Northern India, but it is now proposed that his sphere shall include not only the whole country but also regions beyond the Indian frontier. Accordingly he was sent with the Black Mountain Expedition.

THE British Consul at Costa Rica, in the course of his last annual report, states that a National Museum has been established at San José, and several valuable collections of Indian relics, birds, insects, plants, &c., have been presented or purchased. It is intended that in course of time it shall contain specimens of all the natural products of the country. A national publication and exchange office has also been opened, and all countries are invited to exchange periodicals and publications with Costa Rica.

ACCORDING to a Reuter's telegram from New York, dated October 29, two slight shocks of earthquake had occurred at New Bedford, Massachusetts.

IN the Report of the Committee of Council on Education in Scotland for the past year we find that while 1595 schools taught history and geography only fifty-nine took up elementary science. Strange to say, agriculture is not taught in any of the Scotch training colleges. In the secondary schools, what are called the University subjects—that is to say, Latin, Greek, and mathematics—are very well taught, particularly mathematics. The Technical Schools (Scotland) Act of 1887 has opened, says the Report, to School Boards a new field of operations in regard to a branch of education to which public attention has of late been very closely directed. Only very few schools appear to intend to take action under the Act, chiefly, no doubt, because the Boards are opposed to any increased expenditure. Technical instruction is already given in many of the higher schools. The Report recommends managers of schools in which it is proposed to give technical instruction to secure, if possible, the co-operation of local manufacturers, and to combine with other Boards as pointed out in the Act of 1887.

THE recent meeting of the Congress of American Physicians and Surgeons at Washington seems to have been a great success. It lasted three days, Dr. John Shaw Billings acting as President. *Science* considers that the meeting marked a new departure in national gatherings of American medical men. "It was a con-

vention of specialists," says our American contemporary, "of men who have pursued their investigations, each in his own department, far beyond the point reached by the ordinary practising physician, even though his professional equipment be of the best. The papers that were read, therefore, presented the results of the most advanced scientific researches in the several departments, and the organization of the Congress is such as to insure in the future the maintenance of this high scientific standard. All opportunity for scheming medical politicians to gain prominence or office is carefully guarded against, and the only chance that any physician has to gain distinction through membership of the Congress is by presenting papers of such high order of excellence as to command the attention and secure the approval of the learned members of the medical profession to whom, as to the most competent critics, he submits his work."

AT one of the meetings of the Anatomical Society, during the session of the Medical Congress in Washington, Dr. Lamb, of the United States Army Medical Museum, spoke briefly of a singular phenomenon he had observed in his examination of human breast-bones. It was the occurrence, in a number of specimens, of an eighth rib, the cartilage that is usually found below the seventh rib being fully developed into a rib. Dr. Lamb first saw a specimen of this kind about ten years ago. While teaching, he had occasion to observe the subject he had before the class with great care, and was surprised on one occasion, on counting the ribs, to find that there were eight. He made no further investigation at the time, but recently he has given the subject more attention, and now he has in his own collection four specimens, while in the Army Medical Museum there are eight more. In all these cases the phenomenon occurs in Negroes, but one additional specimen is that of an Indian. *Science* says that Dr. Lamb has made a thorough search of anatomical literature for references to this peculiarity. In the English books there is only a single incidental reference to it, and in that case the author does not say that he has ever seen a specimen. In German books there are two references, one of them being the one already mentioned by the English authority. The French anatomists do not mention it at all; and only one American, Allen, makes any reference to it. Among the anatomists attending the Medical Congress. only two or three had seen specimens. Dr. Billings, in a circular he has sent out to anatomists and others, has requested that information on the subject be sent to the Army Medical Museum.

PART 4 of the Synchronous Weather Charts of the North Atlantic and the Adjacent Continents has been published by the Meteorological Council. It deals with the weather of each day from May 25 to September 3, 1883, and is the completion of the discussion undertaken for the thirteen months from August 1882, in connection with the international system of circumpolar meteorological observations. This last volume of the Atlantic Weather Charts is in every way equal in value to the previous parts issued, notices of which have been given in NATURE. Part 4 represents the weather of the summer season when the conditions over the Atlantic are necessarily quieter than they are in the winter. There is, however, much that is of general interest, and the broken weather so commonly experienced during an English summer is well pictured. Considerable play is shown in the behaviour of the high-pressure area usually situated in Mid-Atlantic, and the direct influence of its movement upon the weather over a very large area of both sea and land is very evident. At the beginning of June the high barometer holds a very central position, and extends across the Atlantic from coast to coast, the barometer reading as high as 30·6 inches. Several low-pressure areas are skirting to the northward, but they are pushed to a higher latitude than usual, and too far to the north to cause any serious disturbance of the weather in the neighbourhood of the British Islands. The high-pressure area, however, soon breaks up, and by June 7 there is no isobar over the Atlantic with a higher value than 30·2 inches, whilst the depressions embrace the whole area to the north of 40° N., and are more serious in character. These unsettled conditions continue till about June 20, when the high-pressure area regains its normal position; but there is somewhat similar play in the high-pressure system shown in July and August, although to a much less extent. The charts show a good instance of storm development in Mid-Atlantic on August 11, which ultimately caused a heavy gale in England on the 14th. A low-pressure area was also formed in 28° N. and 65° W. on August 20, which developed to a hurricane by the 22nd, and apparently reached our islands in a modified form on August 28. Good instances of the movement of depressions are also shown, some disturbances being traced across the Atlantic. An additional sheet is given containing the charts for September 1 to 3, in order to show the passage across the British Islands of a steep cyclonic system which was accompanied by severe gales. The depression apparently originated in 20° N. and 55° W. on August 21, and, after crossing the British Islands at the commencement of September, it passed over the North Sea, and subsequently disappeared.

THE First Annual Report of the Meteorological Society of Australasia, which was established chiefly by the labours of Mr. C. L. Wragge, shows that the Society is making good progress, and now numbers upwards of eighty subscribing members. There are twelve observing-stations established under the auspices of the Society, and it is proposed to establish others in Fiji and Norfolk Islands. The Council also propose to collect observations from ships, with the view of carrying out investigations similar to those undertaken by Dr. Meldrum at the Mauritius. Several papers of interest have been read by members during the past year, and an abstract of the climatological observations is published in the Proceedings of the Society.

TWO remarkable new polymers of methyl and ethyl cyanides, forming well-developed crystals, have been obtained in the laboratory of Prof. E. von Meyer at Leipzig. They possess percentage compositions precisely the same as those of CH_3CN and C_2H_5CN, but twice the molecular weight, and are therefore represented by the formulæ $C_4H_6N_2$ and $C_6H_{10}N_2$. The latter compound was obtained as follows. Metallic sodium, in small pieces, was rapidly added to a solution of ethyl cyanide in absolute ether. A brisk action very soon commenced with formation of a white pulverulent precipitate, and escape of gaseous ethane C_2H_6. After the cessation of frothing, the mixture was warmed upon a water-bath, and the precipitate afterwards separated by decantation, washed with ether, and thrown into water. Decomposition at once occurred, accompanied by the separation of an oil, which on standing solidified in magnificent tabular crystals. These were readily obtained pure by washing with cold water, in which they are but sparingly soluble, pressing between filter-paper, and drying in a desiccator. On analysis they were found to give the same numbers as ethyl cyanide. The latter compound, however, is a liquid boiling at 98° C., while the new substance is a solid melting at 47°–48°. It may be distilled without change, boiling at 257°–258°, 160° higher than ethyl cyanide. Vapour-density determinations show that it possesses twice the molecular weight of the latter compound, a result which was confirmed by determinations according to the new method of Raoult, described in these columns a short time ago. The cycle of chemical changes resulting in the production of this curious polymer have been fully worked out, and are briefly as follows. One atom of sodium appears to replace an atom of hydrogen in one molecule of C_2H_5CN, forming sodium cyan-ethyl, C_2H_4NaCN; a second atom of sodium at the same

time seizes the CN of another molecule, leaving the C_2H_5 to combine with the displaced hydrogen to form ethane. Thus—

$$\begin{matrix} Na & C_2H_5CN \\ + & \\ Na & C_2H_5CN \end{matrix} = \begin{matrix} NaCN + C_2H_5H \\ \\ + C_2H_4NaCN. \end{matrix}$$

The sodium cyan-ethyl then combines with a third molecule of C_2H_5CN to form the sodium derivative $C_6H_9NaN_2$ of the new polymer; this unstable compound is finally decomposed in contact with water, with formation of caustic soda and the new polymer itself. The constitution of this singular compound was conclusively proved to be—

$$\begin{matrix} C_2H_5—C(NH) \\ \quad\quad | \\ \quad\quad CH(CH_3)CN. \end{matrix}$$

In a similar manner the methyl polymer was obtained by the action of sodium upon methyl cyanide, marsh-gas, CH_4, being evolved, and a white substance formed, which, on decomposition by water, yielded the polymer $C_4H_6N_2$ as an oil, eventually crystallizing in white needles melting at 52°–53° C.

THE British Consul at Barcelona, in a report to the Foreign Office on the agriculture of his district, says that a voracious caterpillar which made its appearance in myriads last year amongst the cork forests and stripped the trees completely of their foliage, is now attacked and devoured by another insect, a species of beetle, of a dark-green colour, and armed with a horn with which it cuts up the worms or caterpillars. Besides this deadly enemy, two others are at war with the caterpillar: a crab (*cangrejo*), and an insect, hitherto unknown, which destroys the bags containing the newly-laid eggs of the butterflies. There is very little doubt that the caterpillars will soon be completely exterminated.

A SCHOOL OF FORESTRY has been opened at Akhaltzik, in the Caucasian provinces. The scholars will be selected from the native forest-police actually in the service of the Russian Government. The increased demand made on the forest staff by the law which was passed last April, and which is in force in many districts since July, is the cause of the founding of this school. The officials hope that with an increased staff they will be able to check the devastation of Russian forests.

DR. A. JULIEN AND PROF. H. C. BOLTON have submitted to the New York Academy of Sciences a Report on the results of their researches on sonorous sands. They have collected samples from all parts of the world, and, on close examination, found that all sonorous sands are clean; that no dust or silt is found mixed with the sand; that the diameter of the angular or rounded grains ranges between 0·3 and 0·5 of a millimetre; and that the material may be siliceous, calcareous, or any other, provided its specific gravity is not very great. When these sands are moistened by rain or by the rising tide, and the moisture is evaporated, a film of condensed air is formed on the surface of each grain, which acts as an elastic cushion, and enables the sand to vibrate when disturbed. In sands mixed with silt or dust, these small particles prevent the formation of a continuous air-cushion, and therefore such sands are not sonorous, If this theory be correct, sonorous sand must become mute by the removal of the film of air. Experiments of the authors prove that by heating, rubbing, and shaking, the sand is "killed." All these operations tend to destroy the film of air condensed on the surfaces. On the other hand, samples of sonorous sand were exhibited which had been kept undisturbed for many years. They had retained their sonorousness, but, after having been rubbed for some time, became almost mute. The aim of the authors is now to make a sonorous sand.

MESSRS. A. C. MCCLURG AND CO., Chicago, have issued the fifth edition of "A Manual of the Vertebrate Animals of the Northern United States," by David Starr Jordan, President of the University of Indiana. The work has been wholly re-written, and the order of arrangement is reversed, the lowest forms being placed first.

WE have received the third edition of Mr. Milnes Marshall's well-known text-book "The Frog: an Introduction to Anatomy, Histology, and Embryology." The present edition, we are told in the preface, has been carefully revised, and an account of the development of the frog has been added.

MR. J. RUSSELL has put together a short account of the life and system of Pestalozzi. It is called "The Student's Pestalozzi," and is based on "L'Histoire de Pestalozzi," by Roger de Guimps. Messrs. Swan Sonnenschein and Co. are the publishers.

THE latest issue of the Proceedings and Transactions of the Nova Scotian Institute of Natural Science (vol. vii. Part 2) includes the following papers:—Glacial geology of Nova Scotia, by the Rev. D. Honeyman; list of Nova Scotian butterflies, by Arthur P. Silver; on the elementary treatment of the propagation of longitudinal waves, by Prof. J. G. Macgregor; Carboniferous flora, with attached spirorbes, by the Rev. D. Honeyman; fishes and fish development, by Harry Piers; Carboniferous of Cape Breton, by E. Gilpin, Jun.; Japanese magic mirror, by Harry Piers; museum meteorites, by the Rev. D. Honeyman; and Nova Scotian superficial geology, systematized and illustrated, by the Rev. D. Honeyman. There is also an appendix on birds of Nova Scotia, by Andrew Downs, edited by Harry Piers.

MESSRS. WILLIAM WESLEY AND SON have just issued No. 92 of their "Natural History and Scientific Book Circular," containing an important list of books on botany.

WE have received Mr. J. H. Steward's Catalogue (Part 5) of improved magic and dissolving-view lanterns and slides, with a complete catalogue of photographs for the magic lantern.

THE Calendar of the Huddersfield Technical School and Mechanics' Institute for the forty-eighth session, 1888–89, has been issued. From the report of the Governors for the session 1887–88 it appears that the institution has been making good progress "on every side." The buildings will soon have to be enlarged, and the Governors look forward to the hearty support and co-operation of the town and neighbourhood in this undertaking.

WE learn from *Science* that a manufacturing firm in New York has sent to the United States Department of Agriculture specimens of a new fibre they are making from the stalk of the cotton-plant. The samples received strongly resemble hemp, and seem to be adapted to all the uses hemp is put to. A few fibres of it twisted together in the hand show remarkable tensile strength, although no exact comparative tests with other fibres have yet been made. A collection of the fibres of hemp, flax, jute, ramie, &c., from all parts of the world is being made by the Department, and a new instrument has been invented by which it is expected that the tensile strength of each will be ascertained with great accuracy.

THE additions to the Zoological Society's Gardens during the past week include a Common Seal (*Phoca vitulina*) from British Seas, presented by Mr. Geo. Stevenson; a Tawny Owl (*Syrnium aluco*) from Ross-shire, presented by Mr. J. Weston; a Little Grebe (*Tachybaptes fluviatilis*), British, presented by Mr. Bibby; a Starred Tortoise (*Testudo stellata*) from Ceylon, presented by Mr. William Ford; an Alligator (*Alligator mississippiensis*) from Florida, presented by Mr. G. A. Ruck; a Puff Adder (*Vipera arietans*), an African Cobra (*Naia haje*) from North Africa, presented by Mr. Herbert E. White; a Macaque Monkey (*Macacus cynomolgus* ♂), a Larger Hill-Mynah (*Gracula inter-*

media) from India, three Red Deer (*Cervus elaphus* ♂ ♀ ♀), British, two White-tailed Gnus (*Connochætes gnu* ♂ ♀), bred in Holland; a Ruffed Lemur (*Lemur varius*) from Madagascar, deposited; a Red-crested Pochard (*Fuligula rufina* ♂) from India, purchased.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 *NOVEMBER* 4-10.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on November 4

Sun rises, 7h. 2m.; souths, 11h. 43m. 40·9s.; sets, 16h. 26m.: right asc. on meridian, 14h. 40·3m.; decl. 15° 36′ S. Sidereal Time at Sunset, 19h. 23m.

Moon (New on November 4, 0h., and at First Quarter November 10, 16h.) rises, 7h. 13m.; souths, 12h. 18m.; sets, 17h. 12m.: right asc. on meridian, 15h. 14·5m.; decl. 13° 20′ S.

GEOGRAPHICAL NOTES.

IN some notes embodying the results of his own observations, contributed to the *Mittheilungen* of the Hamburg Geographical Society, Dr. H. Lindemann throws some light on the physical geography of the interior of Heligoland. He points out that the island is protected on the east from the action of the sea by a long and narrow sand-dune, about 1¼ mile distant. The gradual disappearance of this British possession, Dr. Lindemann points out, is but partly due to the action of the sea. This is especially the case with the western side, where the strength of the waves is much greater. The chief factors in wearing down the island are the heavy rainfall, the variations in the weather, and the dissolving power of the frost; all these causes effect the disintegration of the stones and the denudation of the land. The results can be seen better at work on the eastern side of the island, for the strata and the inclination of the Oberland are towards the north-east, and all the water consequently flows that way. The eastern side is largely planted with potatoes, and the gradual disappearance of these potato-fields gives us a tolerably good basis on which to calculate the sinking of this side of the island. There is now nothing remaining of a potato-field which only eighty years ago measured 80 metres, and another field, 25 metres broad, has been reduced within the same period to 3 metres. In old maps we find an ancient cemetery on the eastern side of the Oberland, which had to be removed to its present position. These causes, but, above all, the direction in which the strata lie, produce the different aspect of the eastern and western sides. The eastern cliff is mostly uniform and perpendicular; the western side offers a splendid and varied example of the invasive powers of the sea, with its many inlets, caverns, and chiselled pillars now separated from the main rock. From a comparison with the measurements taken in 1845, Lindemann finds that the western cliff had receded about 7 feet in the last forty years, or at the rate of about 2 inches a year. The Unterland was joined to the dune by a stone jetty, called the Waal, as recently as the seventeenth century. This Waal formed a kind of semicircular harbour, open on the north and south sides. If we take Geern's map, we find the place of the old northern harbour occupied then by green pastures and meadows. But this has all been swept away; the sea carried most of the jetty towards the Unterland and the dune. The destruction of the breakwater had the effect upon the mainland that the Unterland, against which the masses of stone were driven, was gradually so greatly increased that new rows of houses could be built upon the beach.

IT is stated that contracts have been entered into in America for the construction of two steamers intended for an expedition to the Antarctic regions, which is being organized by Mr. Henry Villard. The officers and scientific staff of the expedition will all be Americans and Germans, as the enterprise is stated to be in great part supported by Hamburg money. The expedition will start from New York, and its object will be mainly the exploration of the South Shetlands, South Orkneys, South Georgia, and the Poovel Islands. This expedition seems to be independent of that to be sent out by the German Government under the conduct of Dr. Neumayer.

MR. JOSEPH THOMSON has returned from Morocco in compliance with an urgent telegram from the British East African Company. Mr. Thomson will probably start immediately for Mombassa, and we have reason to believe will be intrusted with a very important mission to the interior.

PRELIMINARY NOTE ON THE ANATOMY AND PHYSIOLOGY OF PROTOPTERUS ANNECTENS.

Introduction.

OWING to the generosity of Prof. Wiedersheim, I have recently had the opportunity of making some observations on the structure and mode of life of *Protopterus*. Although I can at present only give a few brief notes on the subject, some points have already proved so interesting, that it has seemed worth while to give an abstract of my results up to the present time, leaving a detailed description until a later date.

I was fortunate enough to be present in Freiburg at the end of last June when a quantity of fresh material arrived. This was procured direct from the Gambia, owing, in the first instance, to

the energy of Dr. J. Beard, who, assisted by a grant from the Royal Society, hoped by procuring Protopterus in sufficient numbers, and keeping them alive under suitable conditions, to be able to study their development. My thanks are therefore due to Dr. Beard, as well as to Prof. Wiedersheim, for the specimens I have made use of.

The clods of earth in which the animals were inclosed in their torpid state having been opened up, they were found to contain about one hundred living specimens, varying in length from about 8 to 80 cm. These were kept in a tank in the Botanical Garden, in water which stood at a temperature of 18° Réaumur. They were fed with water-snails, earth-worms, Entomostraca, and small fishes, the last of which they seemed to prefer. But the abundant nourishment with which they were supplied did not prevent them from killing one another, so that at the date of writing only a small proportion still remain alive. In order to prevent this cannibalism, we should have isolated them by means of wire-netting, had it not been thought that this would greatly lessen any chance of obtaining embryos. Their vitality is very remarkable: after having been bitten severely, and having consequently lost much blood, they will usually live for some days.

The structure of the "cocoon," and the position of the animal within it, have already been described by Wiedersheim,[1] and in this connection I have only one point to add with regard to the respiration of Protopterus during its torpid state. Although in one or two of the specimens we noticed a slight redness of the tail, I doubt very much whether, as Wiedersheim supposed, the tail serves as a respiratory organ during this period. A close examination of that part of the cocoon-membrane which closes the bottom of the earth-tube, and which overlies the animal's nose, showed that no additional respiratory apparatus was necessary. Looking at this membrane from the outer side, the small aperture described by Bartlett and Krauss can be plainly seen. On the inner side, the rim of this aperture is produced into a funnel-shaped tube, the free end of which lies between the lips of the animal. Consequently, by means of this pipe, the Protopterus can inhale and exhale air during its long sleep. On being removed from the cocoon, moreover, the lungs were always found to be greatly distended and full of air, bubbles of which were immediately given off into the tank in which the specimens were placed. In all probability the above-mentioned tube is produced by suction, when the secretion which gives rise to the cocoon is still soft. The curious squeak which Protopterus makes when set free from the cocoon has been noticed by other observers.

In addition to dissections, and sections of various individual parts, I have made a complete series of transverse sections—in all about 2100—of a small female specimen: these are extremely instructive.

Integument.—Each outer cell of the epidermis is provided with a cuticular cap, and the whole of the epidermis is closely packed with goblet cells, which are less numerous on the paired fins than on the body, where they are less than the diameter of a single one apart. Multicellular glands, very simular to those of Amphibia, are also present here and there throughout the body, and are particularly numerous on the snout. Nests of lymphatic tissue are present beneath the epidermis in some regions.

Muscles.—The chief point of interest I wish to mention concerning the muscles is that they, more particularly the great lateral muscles of the tail, serve as stores of nutriment for the animal during its torpid state. A similar phenomenon has been described by Miescher-Rüsch in the salmon during the spawning season.[2]

The muscular tissue in places shows histologically all stages of retrogressive metamorphosis, and owing to this process, the leucocytes are able to absorb its broken-down remnants, which can be plainly recognized within many of the leucocytes which simply swarm into the muscles in these regions. In some parts the muscle is completely eaten away, so that nothing but the perimysium is left.

Nervous System.—An account of the structure of the nerves, with their numerous spindle-shaped nuclei, and of the remarkable nerve-cells, I cannot give here, and I also reserve at present a description of certain of the cranial and spinal nerves, and of the nerve-supply of the fins. I must, however, mention that the pulmonary nerve crosses its fellow at the base of the lungs, and then runs along the dorsal surface of the lung of the other side. A lateral nerve is situated on either side of the notochord, beneath the muscles, at the point where the dorso-lateral and ventro-lateral muscles meet. The spinal ganglia lie outside the canal. No trace of a sympathetic could be detected.

SENSORY ORGANS.—*Integumentary Sense-organs.*—These are very numerous in the head, and in the body they are not restricted to the main lateral line, but are present in regions above and below it also. They are situated within the epidermis, external to the scales. The moisture necessary for their persistence during the torpid period is produced by the gland-cells of the integument. A mass of lymphatic tissue is usually present directly beneath each: this may be concerned with its nutriment, for it is known that in Amphibians these organs are continually undergoing regeneration. I have been unable to discover any sensory organs in the integument of the paired fins, and the function of these curious filamentous appendages, with their large nerve-supply, is still problematical.

The pharynx is provided with sensory organs similar in structure to those of the integument.

Olfactory Organ.—The structure of the nose is very complicated. In the presence of accessory cavities, it resembles that of Amphibia, but in the folding of the epithelium it is more similar to that of fishes. The main cavity gives rise to dorsal and lateral extensions, the latter corresponding closely with the "pars maxillaris" of Amphibia. Posteriorly, the main cavity branches into a number of tubes, each with a small lumen; these in transverse section resemble gland-tubes cut across. The olfactory cells are in some parts diffuse, in others arranged in groups, as in many fishes and Amphibians.

No special glands are present in connection with the nose, as one would naturally expect. But the moisture necessary for the olfactory cells is probably produced by the numerous goblet cells which are present in the epithelium of the mouth and that lining the anterior and posterior narial passages. This may explain the peculiar position of the anterior nostrils, which open beneath the upper lip.

Eye.—No gland is present within the orbit. The lens is globular and relatively large, filling up the greater part of the posterior chamber, so that there is little space left for the vitreous body. The sclerotic is fibrous, but a few cartilage cells can be recognized in those regions in which the eye-muscles are inserted. The choroid is rudimentary, and contains no pigment, and there is no iris or pupil, the pupillary membrane being continuous over the front of the lens. The epidermis thins out slightly over the eye, and in this region the goblet cells are smaller and less numerous. The dermal fibres are directly continued on the one hand into the representative of the cornea, and on the other into the sclerotic. Processes of the pigment cells of the retina can be seen passing between the rods and cones. No trace of a processus falciformis could be seen.

ALIMENTARY CANAL.—*Lips.*—No muscles are present in connection with the lips, as is stated to be the case by Ayers.[1] Beneath the epidermis they consist of a curious embryonic connective tissue very rich in nuclei, similar to that found in the snout and tongue.

Tongue.—The tongue is covered with numerous filiform papillæ in older specimens, the histological structure of which I have not yet examined. None are present, however, in the sections of a younger specimen. Goblet cells are very numerous in the epithelium, which is folded so as to give rise to a number of simple gland-like sacs. No sense-organs can be seen in my sections. The extrinsic muscles are, on either side, (1) a large hyoglossus, and (2) a small band-like branchioglossus. There are no intrinsic muscles, the whole of the substance of the anterior part of the tongue beneath the epithelium consisting of the connective-tissue referred to above.

On the floor of the mouth, in front of the tongue, and between the two cusps of the mandibular teeth, is a curious tube-like epithelial organ which apparently opens by a small aperture near its posterior end into a median groove of the oral epithelium. This tube is lined by columnar epithelium with goblet cells.

Thyroid.—The thyroid is a small bilobed organ, situated between the connective-tissue and muscular portions of the tongue. Its epithelium is flat, and the tubules contain a colloid mass which stains deeply.

Thymus.—The well-developed thymus consists of adenoid connective-tissue with leucocytes, and lies on the dorsal side of

[1] *Anat. Anzeiger*, II. Jahrgang, 1887; and Proc. Brit. Assoc., 1887.

[2] "Ueber das Leben des Rheinlachses im Süsswasser," *Archiv. f. Anat. u. Physiol.*, 1881.

[1] "Beiträge z. Anat. u. Physiol. der Dipnoër," *Jen. Zeitschr. f. Naturwiss.*, Bd. 18, 1885.

the gill-arches. Black pigment is present in the anterior part of its inner portion.

Epithelium.—The epithelium lining the mouth consists of polygonal cells, apparently without cilia. In the pharynx, nests of simple glands, like those of the tongue, are present; and, as already mentioned, numerous sense-organs are to be found in the region of the gill-clefts. The epithelial cells of the stomach and intestine are columnar, but vary much in their form and proportions. Cilia could be detected here and there; in all probability they occur in isolated regions, as in the adult lamprey.

With the exception of the large liver, there is no trace of any gland in connection with the stomach and intestine, and digestion must be thus performed largely through the instrumentality of leucocytes.

Muscles of the Alimentary Canal.—The muscles of the walls of both stomach and intestine are only very slightly developed in torpid specimens, and are apparently broken up and separated by the lymphatic tissue to be described presently. They probably, therefore, undergo a similar degeneration to that observed in the caudal muscles.

Lymphatic Organs of the Stomach and Intestine.—The form of these organs has been described by Ayers (*loc. cit.*) I have not been able to verify his supposition that there are direct connections between them and the lumen of the intestine. A central part of the lymphatic organ running down the axis of the spiral valve can be distinguished from the rest by its more compact structure. Many of the leucocytes in these regions are full of fat-globules.

A large lymphatic body is present behind the cloaca and pelvis, and probably serves to protect the vent from the entrance of harmful substances.

Cloacal Cæcum.—The so-called "urinary bladder" opens into the cloaca between the rectum and the urinary and generative ducts. It has therefore much the position of the "rectal gland" of Selachians, and probably has nothing to do with the urinary bladder of other forms.

Lungs.—The cavity of the lungs is divided up by trabeculæ, which give the anterior unpaired portion a sponge-like appearance: a central lumen is present in the paired portion. A large lymphatic organ lies beneath the anterior unpaired part, the curious relations of which I hope to describe later, and will now only mention that the blood corpuscles migrate from it into the tissues of the lung.

Abdominal Pores.—As Ayers has shown, only one abdominal pore is usually present, and in my sections this ends blindly, and does not open into the cœlome. Probably its relations vary in different individuals.

Blood Corpuscles.—The chief peculiarity of the blood of Protopterus is the large size of the corpuscles, and the comparatively large proportion of the white in comparison with the red. The form of the latter resembles that of the red corpuscles of Amphibians. In length they measure from 0·040–0·046 mm., and in width 0·025–0·027 mm. The size of the white corpuscles varies greatly. The diameter of the largest, when not throwing out pseudopodia, may exceed the length of a red corpuscle. Two kinds may be distinguished, as follows:—(1) Large leucocytes of the ordinary form, the protoplasm of which is usually distinctly differentiated into a coarsely granular endoplasm and a hyaline ectoplasm. In specimens prepared for me by Dr. Goldmann, according to Dr. Ehrlich's method, the protoplasm and nucleus are coloured violet. (2) Leucocytes of various sizes, the largest being usually rather smaller than those described above. The granules in the protoplasm are finer, and in addition to the ordinary blunt pseudopodia, stiff filamentous processes are also formed. The protoplasm of these stains brownish-red by Ehrlich's method, and Dr. Goldmann informs me that a similar coloration occurs in human white corpuscles in cases of leukæmia. Prof. August Gruber was kind enough to make a careful examination of these corpuscles with me, and we were able to trace a gradual disintegration in those described under (2), until finally nothing but the greatly altered nucleus is left. It seems probable, therefore, that these leucocytes convey the nutriment from the alimentary canal (or muscles) into the blood, and there disintegrate.

Blood-vessels.—I have at present only one or two remarks to make on the arrangement of the blood-vessels. Hyrtl's description [1] of the vessels of Lepidosiren would answer equally well in most points to Protopterus. Peters [2] describes a single pulmonary artery, arising from the efferent branchial vessels on the left side. This soon branches into two, each branch running along the inner side of the corresponding lung. No mention, however, is made by Peters of the corresponding right vessel, which has precisely the arrangement described by Hyrtl in Lepidosiren. This right pulmonary artery also divides into two, one branch passing along the dorsal surface of each lung alongside the pulmonary branch of the vagus.

The caudal vein divides up into two renal-portals. These are said by Hyrtl to anastomose anteriorly with a paired azygos in Lepidosiren. I have been unable to find any such "azygos vein" in Protopterus. The two so-called "venæ cavæ posteriores" doubtless correspond to the posterior cardinals, though they are somewhat modified. No lymphatic vessels could be detected.

Urinary Organs.—The kidneys are closely invested everywhere except on their dorsal side, by lymphoid and fatty tissue, which posteriorly forms a large median mass, plugging the end of the cœlome. No nephrostomes are present, as was supposed by Ayers.

A quantity of pigmented tissue on the outer and lower borders of the kidneys may possibly represent the adrenals.

Generative Organs.—Concerning the structure of the female generative organs, I have, as yet, little to add to the descriptions of former observers. No accurate account of the male organs exists, and I am inclined to think that the descriptions which have been given up to the present time referred to immature females, the generative organs of which might easily be taken for those of a male.

I have been able to distinguish no essential differences in external form between males and females: the latter are by far the more abundant.

Each testis has much the form and relations of an immature ovary, and, like the ovary, is invested along its free edge and sides with lymphatic and fatty tissue. Along its ventral surface a slight groove can be distinguished, at the bottom of which the spermatic duct lies. Posteriorly, the two ducts come to the surface, unite, and open by a common aperture on a papilla into the cloaca, just as in the female. In transverse sections, the seminiferous tubules can be seen opening into the ducts; in ripe specimens, fully formed spermatozoa can be seen in their lumina. I have, up to the present time, found nothing which could correspond to the remnant of a Müllerian duct, and, as the ureter undoubtedly must represent the mesonephric duct, there remains no other explanation of the duct of the testis than to suppose it to be the homologue of the Müllerian duct.

The form of the spermatozoa is very curious: they are carrot-shaped, and each is provided with two long cilia. They are very small, the length of the carrot-shaped head being only about 1/25 mm.

Most of the above observations were made in the Anatomical Institute in Freiburg i/B, where I have profited much by the kind help and advice of Prof. Wiedersheim.

August 31, 1888. W. NEWTON PARKER.

A more detailed examination of a male specimen, in which the spermatozoa were not yet ripe, has shown that distinct rudiments of the anterior parts of the Müllerian ducts are present. Each has an abdominal aperture, similar in form and position to that of the oviduct, and extends backwards for a short distance, tapering off before the level of the kidneys is reached. In sexually mature individuals, all traces of the Müllerian ducts appear to have vanished.

The duct of the kidney must therefore, as in Elasmobranchs, represent a special collecting-tube developed in connection with the posterior mesonephric tubules. W. N. P.

THE WHEAT CROP OF 1888.

SIR JOHN LAWES has communicated some interesting facts with regard to the wheat crop of the present year. It has been Sir John Lawes's endeavour for many years past to establish a statistical relation between the fluctuations of the yield of wheat upon his own well-known experimental field in Hertfordshire with the general average obtained over the United Kingdom. In order to do this he has selected certain plots and taken their average yields, and it is maintained that the result so obtained fairly represents the average yield over the United Kingdom.

This conclusion is based upon observations extending over upwards of forty years, and has been rather forced upon the attention of Sir John Lawes, than assumed in the first instance.

The central position of Hertfordshire (at least with regard to England), and the medium character of the soil and climate, afford some reason for expecting an average yield; and the various treatments to which the selected plots have been subjected also assist to secure an average and representative result. The selected plots are five in number, each of which has been similarly treated for the last forty-five years, and all of them have carried wheat every year during this long period. One of these plots has remained continuously unmanured and has yielded on an average 13 bushels per acre, which, strange to say, is one bushel above the official average crop of the United States of America. One has been continuously manured with fourteen tons of farmyard manure per acre, and has yielded an average of $33\frac{3}{4}$ bushels during the last thirty-six years. The remaining three selected plots have been treated with artificial manures upon a uniform and undeviating plan, and have yielded on an average respectively $32\frac{3}{4}$, $36\frac{1}{2}$, and $36\frac{3}{4}$ bushels per acre taken also over a period of thirty-six years.

The mean average of all these five plots taken over this long period is $27\frac{5}{8}$ bushels, and it is this *mean* which corresponds with, or at least closely approximates to, the average yield of the United Kingdom. The average yield of these five selected plots for the present year is $27\frac{5}{8}$ bushels per acre, equal to $26\frac{5}{8}$ bushels when calculated as of 61 pounds each. The average yield arrived at on the same principle last year was $28\frac{3}{8}$ bushels per acre, showing a deficit this year as compared with last of $1\frac{1}{2}$ bushel per acre. Again, comparing the result obtained from the Rothamsted standard plots with what is considered the usual standard average of 28 bushels per acre, the deficiency for the present year would appear to amount to $1\frac{1}{8}$ bushel per acre only.

Sir John Lawes's general deduction that the selected plots at Rothamsted fairly represent in yield the average of the United Kingdom is certainly an assumption which might be objected to on scientific grounds. It is, however, as already pointed out, rather to be regarded as an ascertained fact than as a simple assumption, and from the evidence of a large number of years, the fluctuations of yield at Rothamsted may be regarded as a barometer, if we may so express it, of the parallel fluctuations throughout the United Kingdom.

Judged by the standard of the Rothamsted yields, the wheat crop of 1888 is only slightly below the received average of 28 bushels per acre.

It is well known to agriculturists that the harvest of 1879 was the worst which the present generation has witnessed, and during the dismal summer which has now ended, many persons expressed an opinion that the harvest of 1888 was likely to equal in badness that of 1879. This discouraging view has, however, happily been dispelled, and the harvest of 1888, although inferior in both quantity and quality to an average one, is not to be reckoned as disastrous.

One important feature of the harvest of 1888 is, however, its irregularity, and this has not only given rise to many conflicting opinions, but made it exceedingly difficult to arrive at the truth.

The opinion of Sir John Lawes is that upon farms where the condition of the land was defective, as well as upon all lands where there was an excess of artificial nitrogenous manure, there was less than the average produce; but that when the manurial conditions were more favourable there was more than an average produce. Thus the continuously unmanured plot yields only 10 bushels per acre instead of 13, the average of the preceding 36 years. The farmyard manure plot, on the other hand, yields 38 bushels, against an average of only $33\frac{3}{4}$ bushels. Lastly, the plot which receives an excessive amount of nitrogenous manures in the form of ammonia salts, as well as mineral substances, yields only $35\frac{1}{4}$ bushels, against its average of $36\frac{1}{2}$ bushels. The result thus generally indicated is supported by experiments made beyond the list of the usually selected plots, and is in these experiments still more pronounced.

The economic conclusion arrived at by Sir John Lawes after carefully passing this evidence in review is that "Taking the average population of the United Kingdom for the harvest year 1888–89 at rather over $37\frac{3}{4}$ millions, the estimated requirements for consumption, at 5·56 bushels per head, would be about $26\frac{5}{8}$ million quarters. The area under wheat is reported to have been 2,663,436 acres, or nearly 300,000 acres more than last year. This area, at $26\frac{5}{8}$ bushels per acre, would yield nearly 9 million quarters (8,947,480), and deducting 2 bushels per acre for seed, there would remain rather over $8\frac{1}{4}$ million quarters (8,281,621) available for consumption, and there would therefore be required about $18\frac{1}{4}$ million quarters (18,394,271) to be provided from stocks and import. It is admitted that the wheat crop not only of America, but of some other countries whence we derive supplies, will be below the average. But during the last two months of the past harvest year our imports were at the rate of 21 million quarters per annum, and there seems no reason to fear that there will be any difficulty in obtaining sufficient supplies."

ON THE INFLUENCE OF LIGHT UPON THE EXPLOSION OF NITROGEN IODIDE.[1]

THE statement of L. Gattermann in his recent paper (*Berichte d. deutsch. chem. Gesellsch.* xxi. 751; following up V. Meyer's paper in the same volume, p. 26) on nitrogen chloride, that its explosive decomposition may be brought about, or its susceptibility to explosion much increased, by exposure to bright light, has recalled to my mind the fact, which did not specially impress me at the time, that I myself undoubtedly observed the same relation several years ago in the case of nitrogen iodide.

In a paper on the preparation and composition of the latter substance, published in the first number of this *Journal* (April 1879), it was noted that on two occasions the product obtained with the composition NI_3 or N_2I_6 "exploded in some quantity *under water* with much violence and complete shattering of the vessel."

I remember distinctly that in one of these cases I had just carried to a window, through which the sun was shining, the beaker full of water at the bottom of which was the black sediment of iodide, and was gently stirring the liquid with a glass rod, holding the beaker up so as to look at it from below, when the rod touched the lower part of the side or the bottom of the vessel, and the explosion occurred.

In the other case the iodide was being washed with ice-cold water of ammonia, the vessel standing on a table exposed at the time to the direct rays of the sun. I do not remember with certainty what seemed to precipitate the explosion on this occasion, but I believe it was the pouring some fresh liquid, from the height of a few inches, on the black sediment of iodide which had just been partially drained by decantation.

Under ordinary circumstances nitrogen iodide, while *wet*, exhibits no extraordinary sensitiveness, and may be safely worked with, only becoming highly dangerous on drying, so that I have little doubt that bright sunshine was influential in bringing about these two explosions.

J. W. MALLET.

University of Virginia, May 8, 1888.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Dr. Hill, now Master of Downing College, having resigned the Demonstratorship of Anatomy, a senior demonstrator and two junior demonstrators at £100 and £50 stipends, and a University lecturer on advanced human anatomy are to be appointed, providing four teachers for the aggregate stipend, £250, formerly received by the Demonstrator. Starvation pay this, considering the limited opportunities in Cambridge for supplementing the income of an anatomist.

A grant of £80 from the Worts Fund is recommended to be made to Mr. M. C. Potter, to enable him to make botanical researches and to collect specimens in Ceylon during the coming winter.

The old Chemical Laboratory being now vacant, it is to be altered into a Pathological Laboratory for Prof. Roy.

The new scheme of examinerships in natural science was passed last week; the chief features being the appointment of two examiners each in elementary biology and chemistry, to take the 1st M.B., and the "specials" for the ordinary B.A. The stipends are rearranged, and in addition to a fixed amount a proportionate sum per candidate is allotted to the examiners, 5*s.* for Tripos candidates, 4*s.* for 2nd M.B. physiology and anatomy, and 2*s.* for the rest. Thus the examiners in anatomy and physiology, if 100 candidates

[1] Reprinted from the *American Chemical Journal*, vol. x. No. 4.

present themselves for the Tripos and 100 for 2nd M.B., will receive £75 each. The papers of all candidates in a subject are to be looked over by both examiners, who must be present at all oral examinations and at the final meeting of examiners.

The Harkness Scholarship in Geology and Palæontology, for women in their first or second term of residence, has been awarded to E. Macdonald, of Girton College.

H. F. Newall, M.A. of Trinity College, has been recognized as a teacher of physics, D. Carnegie, B.A. of Caius College, as a teacher of chemistry, and J. R. Vaizey, M.A. of Peterhouse, as a teacher of botany, for the purpose of giving certificates for M.B. degree.

At Jesus College, on December 11, there will be an examination for scholarships in natural science, the maximum value being £80. Notice must be given to the tutors before December 1. Chemistry is essential, and one of the following: physics, elementary biology, animal physiology. Christ's College examination will commence on the same date, and a candidate may be elected at either College.

At St. John's College the open scholarship examination on December 11 may include all the subjects of the Natural Sciences Tripos, but every candidate must show a competent knowledge of two of the following subjects: elementary physics, chemistry, and biology.

SCIENTIFIC SERIALS.

American Journal of Science, October.—On a young tortoise with two heads, by E. H. Harbour. An account is given of a two-headed *Chrysemys picta* recently found near New Haven, Connecticut, and presenting some interesting physiological features. They appear to be two independent organisms inclosed in a common carapace, with separate and even antagonistic instincts and impulses, as shown in their struggles to move in opposite directions, in their independent breathing, sleeping and feeding at different times, and so on. They were still alive and vigorous on September 4, fourteen weeks after capture.—The structure of Florida, by Lawrence C. Johnson. In this paper, which was read before the American Association for the Advancement of Science at New York last year, the peninsula is divided longitudinally into four regions plainly marked by surface indications: (1) the Gulf Hammock in the west; (2) a central plain, or region of sinks; (3) the High Hammocks, or lake region; (4) the eastern slope, draining to the St. John's River.—Analysis of a soil from Washington Territory, with some remarks on the utility of soil analysis, by Edward A. Schneider. The specimens here analyzed are from the Rockland Ridge near "The Dalles" on the Columbia River. From this study the author infers that the action of hydrochloric acid on soils is far from uniform; that plant roots probably derive their nutrition from the finest sediments of the soil; that hydrochloric acid powerfully corrodes both the finest and coarsest sediments; that fertility largely depends not only on the quantity of phosphoric acid, but also on the mode of its occurrence, and that consequently the fertility of a soil cannot be determined by chemical analysis alone.—On the Rosetown extension of the Cortlandt series, by J. F. Kemp. The discovery of this extension of the well-known Cortlandt series is accredited to Dr. N. L. Britton, and the Rosetown area, due west of Stony Point, is here definitely circumscribed.—The contact-metamorphism produced in the adjoining mica-schists and limestones by the massive rocks of the Cortlandt series near Peekskill, New York, by George H. Williams. In previous papers were described the principal types and some intermediate varieties forming the complicated group of this series. Here the author deals with the unusual contact-metamorphism which they have occasioned in the adjoining schists and limestones, concluding with a summary of the evidence in favour of the eruptive origin of the massive members of the series.—The sedentary habits of Platyceras, by C. R. Keyes. The sedentary habits of this group of Palæozoic Gastropods is inferred from the analogous habits of their modern congeners, and from their attachment to various species of Crinoids during life.—On edisonite, a fourth form of titanic acid, by W. E. Hidden. The specimen here described is from the Whistnant gold mine, Polk County, California. Its analysis shows it to be a nearly pure TiO_2, like rutile, but differing in its crystallization from the three previously known forms of that mineral.—On two new masses of meteoric iron, by George F. Kunz. The first of these specimens, from Linnville Mountain, North Carolina, closely resembles the Tazewell, Claiborne, and Bear Creek (Colorado) meteorites in composition; the second, from Laramie County, Wyoming, approaches nearer to those of Rowton, Charlotte, and Jewel Hill.—Experiments on the effect of magnetic force on the equipotential lines of an electric current (continued), by E. H. Hall. An account is here given of the author's experiments with cobalt, nickel, and bismuth, together with a summary of results.—W. Spring gives a further account of his views regarding the compression of powdered solids, in reply to Mr. Hallock; and E. S. Dana contributes a short preliminary notice of beryllonite, a new mineral so named by him from the fact that it contains the rare element beryllium.

THE *American Meteorological Journal* for September contains:—(1) An article by Prof. J. E. Curtis on suction anemometers. Two different forms of such instruments have been proposed, corresponding to two distinct ways in which a moving fluid produces a diminution of pressure. In the first the suction is produced by the wind blowing through a horizontal tube, having a contracted section; in the second the suction is produced in a vertical tube, by the wind blowing across its mouth. The second form alone has come into limited use, under the name of the Hagemann anemometer. The author points out that these instruments are not more generally used partly because there is a feeling of uncertainty as to the definite relation of the suction to the wind's velocity. The paper deals almost exclusively with their history and theory. (2) An account by Mrs. J. N. Brodhead of her experience of the great cyclone at Calcutta, on October 5, 1864. (3) An article by Prof. H. A. Hazen on the advantages of Mount Washington as a meteorological station. No individual station has had its observations discussed more thoroughly, and one of the most important investigations has been the use of the observations in determining a proper reduction of barometric readings at great altitudes to sea-level, by Lieut. Dunwoody.

Bulletin de l'Académie des Sciences de St. Pétersbourg, vol. xxxii. No. 3.—On the determination of constants of the ellipsoid of the earth by means of geodetical measurements, by A. Bonsdorff. This paper contains new formulæ for the calculation of the eccentricity.—On the formation of meteoric currents from the disintegration of comets, by Dr. C. Charlier, being a mathematical inquiry into the orbits of meteorites.—On the aberration of fixed stars, by M. Nyrén. After having calculated it on the ground of observations of two stars, the Comes and the Polaris, M. Nyrén obtains very nearly the same numerical values as those formerly found for the same stars by W. Struve.—On a new method for determining the focal distance of a system of lenses for different rays of light, by Dr. Hasselberg.—Some remarks on the fables of Phædrus, by A. Nauck.—A note by Dr. W. Radloff on grave-inscriptions in Semiryetchensk.—On the phenyl-angelic acid, by A. Gernet.—The approximate elements and ephemerides of Encke's comet for 1888, from May 12 to August 28, by O. Backlund and B. Seraphinoff.—The tale of the Princess Bentres compared with the tale of the Emperor Zenon and his two daughters, by Dr. O. Lemin. (All in German.)

No. 4.—Diagnoses of new Asiatic plants, by Dr. C. J. Maximowicz, being the seventh instalment (in Latin, with four plates) of a capital work about new plants brought by Przewalski, Potanin, Taschiro, and several others, from Central Asia, Japan, &c.—On the "hyperelementary" terms in the theory of perturbations, a mathematical inquiry, by O. Backlund (in German).

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 22.—M. Daubrée in the chair.—On lameness caused by pain, by M. Marey. By means of his photo-chronograph the author studies the character of the peculiar limping action instinctively caused by the desire to diminish the pain of a sore foot in walking. From the standpoint of the mechanical laws regulating the pressure of the foot on the ground, the three cases are considered in which this pressure is either equal to, greater, or less than, the weight of the body.—A paper follows by the same author, in which the swimming action of the eel is studied and illustrated by the same photo-chronographic process. The eel was 0·30 m. long, reduced by its squirming action to 0·29 m., and its rate of progress was shown to be 0·019 m. in 0·1 second, or about

0·19 m. per second.—Elements and ephemeris of Barnard's comet, by M. E. Viennet. The comet here in question was discovered on September 2, 1888, by Mr. Barnard, at the Lick Observatory, California, and noticed two days afterwards by Mr. Brooks, of the Geneva (U.S.) Observatory. The observations on which these elements are calculated were taken on September 5 and 18, and October 1, the first at Besançon, the two others at Hamburg.—On some errors affecting the observations of transits, by M. Gonnessiat. The sources of error here discussed are the magnitude of the stars on the one hand, and their position on the other. In the latter case, the absolute error is shown to decrease rapidly to within about 2° of the Pole, after which it becomes pretty constant. Hence in determining the instrumental constants, the stars nearest the Pole should be preferred.—Reflected images on the spheroidal surface of the Lake of Geneva, by M. F. A. Forel. M. Riccò's recent note (*Comptes rendus*, cviii. p. 590) showed the deformation of the image of the sun reflected by the spheroidal marine surface. The observations now taken by M. Forel on the Lake of Geneva fully confirm the interpretation of the Sicilian astronomer. Attention is called to the fact that the theoretical demonstration of the probability of such deformations was first given by M. Ch. Dufour, of Morges. This new demontration of the rotundity of the globe is now no longer theoretical, but is borne out by the direct observation of the phenomenon.—On the intersection of two algebraic curves in a single point, by M. G. B. Guccia. Several geometricians have long been engaged on the inquiry into the number I. of the intersections of two curves, $\phi = 0$, $\psi = 0$, merged in a single point, P. Prof. Cayley and M. Halphen have given general solutions of this extremely delicate problem, and M. Guccia has now been incidentally led to a new general expression of the number I., which presents considerable interest thanks to its great simplicity as well as the numerous and easy applications of which it is capable.—On the combination of benzoic aldehyde with the polyatomic alcohols, by M. Maquenne. In a recent note on the valency of perseite the author described, under the name of *dibenzoic acetal of perseite*, a new compound analogous to that obtained by M. Meunier with mannite and benzoic aldehyde. He now shows that in the acetals derived from a polyvalent alcohol each molecule of aldehyde necessarily saturates two alcoholic functions. If the number of the latter is odd, the aldehyde will always leave at least one free, whence it results that the elementary composition of these acetals, in passing from any polyatomic alcohol to its next homologue, differs sufficiently for them to be at once distinguished by analysis. Here is therefore a new means of determining whether an alcohol is of odd or even atomicity.—Action of hypophosphorous acid on benzoic aldehyde; formation of a dioxyphosphinic acid, by M. J. Ville. M. W. Fossek has obtained acid crystallized products corresponding to the general formula—

$$R—CH,OH—PO(OH)_2,$$

which he calls oxyphosphinic acids. But no chemist had hitherto determined the existence of dioxyphosphinic acids. M. Ville, however, has now obtained a compound belonging to this new class of acids. The process, as here described, consists in making hypophosphorous acid act on benzoic aldehyde. It may be designated by the name of dioxybenzylene-phosphinic acid, its constitution being expressed by the formula—

$$\begin{array}{c} C_6H_5—CH\ .\ OH \\ | \\ PO\ .\ OH \\ | \\ C_6H_5—CH\ .\ OH. \end{array}$$

—M. G. Denigès describes the action of the hypobromite of soda on some aromatic nitrogenous derivatives, and the differential reaction between the hippuric and benzoic acids.

BERLIN.

Physical Society, October 19.—Prof. von Helmholtz, President, in the chair.—Dr. König gave an account of experiments which he had made with Ottomar Anschütz on the instantaneous photography of projectiles. After exhibiting and explaining the instantaneous photographs which Anschütz had made during the last few months, such as those of the funeral procession of the late Emperor Frederick, of episodes at the manœuvres, of wild beasts at the Zoological Gardens in Breslau, of the several positions of a soldier marching on parade, and of a lady dancing, he described the arrangements necessary for photographing a cannon-ball travelling at the rate of 400 metres per second. The cannon-ball was projected in front of a white screen illuminated by direct sunlight, occupying in its passage $\frac{1}{75}$ second: during this time four negatives were taken. The firing of the cannon, the momentary exposure of the plate, and the recording of time on the chronograph were provided for by electric currents. The experiments were made at Magdeburg at the Grüson rampart, and had to be completed in one day. Only one successful picture of the projectile was obtained, but the possibility of such experiments, and of the accurate determination of the several time intervals, were sufficiently indicated.—Dr. Budde spoke on the mechanics of forces acting on rigid bodies. As one outcome of this address may be mentioned a proposal of Dr. Budde's with respect to the nomenclature of conjugate forces. Ordinarily, of two conjugate forces only the second one is spoken of as conjugate, while no special name is given to the first. The speaker therefore proposed to call the first of two conjugate forces "male" and the second "female," and introduced this nomenclature into his address with very marked furtherance of its clearness.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Studies from the Morphological Laboratory in the University of Cambridge, vol. iv. Parts 1 and 2 (C. J. Clay).—Life of Sir William Siemens: Wm. Pole (Murray).—Die Gletscher der Ostalpen: Dr. E. Richter (Englehorn, Stuttgart).—Force and Energy: Grant Allen (Longmans).—Theoretical Mechanics: J. E. Taylor (Longmans).—Elementary Theory of the Tides: T. K. THURSDAY, NOVEMBER 8, 1888.

THE PREVENTION OF SMOKE.

THE people of London have lately experienced much inconvenience and discomfort from the dismal fogs which so often make their appearance at this season of the year. Considerable interest, therefore, attaches to the excellent lecture, by Mr. Rollo Russell, on "Smoke in Relation to Fogs in London," of which we to-day print an abstract. The importance of the subject no one will dispute, yet the questions connected with it have hitherto received very inadequate attention. That much might be done to purify the atmosphere, not only of London, but of all our great towns, is certain; what is needed is simply that the matter shall be taken in hand in earnest by the Legislature. The existing Acts of Parliament to abate the nuisance arising from the smoke of furnaces in the capital are efficient so far as they go. Inventors have produced mechanical stokers and other means of feeding furnaces, which have resulted not only in the prevention of smoke from such furnaces, but also in commercial advantages to their users, by reason of the increased efficiency and reduced consumption of the furnaces. Police-inspectors appointed to watch the chimneys of manufacturers' premises have done most useful work in preventing the emission of smoke, and London is to be congratulated upon the freedom from smoke from such sources. Legislation, however, has not gone far enough even in controlling the emission of smoke from furnaces, for in the provinces there is very great negligence. In some places by-laws exist, in other places there are none; but wherever they are enforced it is invariably the case that the fines imposed are too small, and that the real offenders, the manufacturers and users of the furnaces, do not adequately feel the effect of the penalties in which they are mulcted.

The careful observer in London will find that the nuisance from which we suffer does not arise from factory or other industrial chimneys, but from the millions of domestic chimneys. Why should legislation apply only to the comparatively small number of industrial furnaces in London, and leave the multitude of hotel and private fire-places to emit dense volumes of smoke? In a letter addressed some time ago to the *Times*, Mr. Alfred E. Fletcher clearly demonstrated the practicability of having open fire-places in well-warmed and thoroughly ventilated houses without smoke, but there is no law to enforce the application of such a system. To those who have not read Mr. Fletcher's letter, the apparatus may be briefly described. It consists of a coke stove in the basement, a flue to discharge products of combustion, an air-pipe drawing in air around the stove and discharging it when warmed through a grating on the ground-floor. The effect of this simple apparatus is such that warm, but not scorched, pure air ascends up the staircases, into the rooms, passes up the chimneys, and out at the windows, without creating draughts of any kind. The open fire-places in all the rooms may be maintained, but, to insure their smokelessness, they should either have one or other of the systems of under-feeding coal grates, or have incandescent blocks heated by gas. The duty of the fire-place is reduced to practically nothing, as the whole house is warmed by pure air from the heating chamber of the coke stove, and the bright open fire need only be maintained to satisfy English prejudice and custom.

This is one system which has come under our notice, and others might be mentioned. But one fact is enough—viz. that ordinary London houses can be thoroughly well warmed with pure air, well ventilated by known appliances, and with this knowledge the public ought to demand immediate legislative action. There is evidence that the necessity of legislation is beginning to be understood, for the House of Lords was some time ago approached by Lord Stratheden and Campbell with a Bill "to amend the Acts for abating the nuisance arising from the smoke of furnaces and *fire-places* within the metropolis;" and, although this Bill did not pass into law, its importance was such that a Select Committee was appointed to consider its terms and to report to the House of Lords. Mr. Ernest Hart gave many thoroughly practical suggestions for the prevention of smoke from domestic fire-places in his evidence before the Select Committee; and other evidence from scientific, legal, and police authorities was adduced. But at the time the public interest in the question was insufficient to secure the passing of the measure.

If members of the Houses of Lords and Commons would seriously consider the dangers to life, the inconvenience, the loss, the injury to household effects, and other disadvantages which the presence of smoke and other impurities in the air occasion, and would turn their attention to the very deficient legislative measures now existing, a speedy remedy would no doubt be effected. The necessity for the universal adoption of smoke-preventing appliances would probably bring out much latent inventive talent from the public. By reference to the Report of the Council of the National Smoke Abatement Institution, we find that inventors and manufacturers are continually introducing better means of consuming fuel. The greatest improvement is in apparatus for industrial furnaces, because it is with these appliances only that Acts of Parliament deal. As compared with some tests made by the Smoke Abatement Institution in 1881–82, tests made in 1886–87 show an apparent economy of 31 per cent. in consumption of fuel combined with complete smoke prevention. In the Transactions of the Sanitary Institute of Great Britain—in a paper on smoke abatement, read by Mr. Russell Duncan at the Bolton Congress—we find that inventors are working in the right direction, and that during the last ten years over 4200 patents have been taken out for various appliances having for their object the prevention of smoke and the more complete combustion of fuel.

An examination of the work done by the National Smoke Abatement Institution will show that if legislative measures could be carried it would not be necessary to restrict the use of one kind of fuel in favour of another, but that by means of suitable appliances houses might be heated by ordinary fuels—coal (bituminous and non-bituminous), coke, oil, and gas, or by improved systems of circulating warmed air and heated water.

SOME RECENT MATHEMATICAL BOOKS.

Euclid. Part 1, Books I. and II. By H. S. Hall and F. H. Stephens. (Macmillan, 1887.)

Algebraical Exercises. By H. S. Hall and S. R. Knight. (Macmillan, 1887.)

Key to Todhunter's Mensuration. By Rev. L. McCarthy. (Macmillan, 1886.)

Explanatory Arithmetic. By G. E. Spickernell. Third Edition. (Simpkin, 1887.)

Plane and Spherical Trigonometry. By H. B. Goodwin. (Longmans, 1886.)

Spherical Trigonometry. Part 2. By W. J. McClelland and T. Preston. (Macmillan, 1886.)

Solid Geometry: Solutions. By P. Frost. (Macmillan, 1887.)

Elementary Statics. By J. Greaves. (Macmillan, 1886.)

Differential Calculus. By B. Williamson. Sixth Edition. (Longmans, 1887.)

Differential Calculus. By J. Edwards. (Macmillan, 1886.)

Algebra. By Oliver, Wait, and Jones. (Ithaca: Finch, 1887.)

Practical Solid Geometry. By W. G. Ross. (Cassell, 1887.)

IF former periods of the world's history were characterized as the "Stone," "Bronze," and "Iron" Ages, the present epoch might well be entitled the "Book" Age. Amidst the flood of literature of all sorts which daily pours out of the jaws of our printing leviathans, didactic mathematics certainly claims its due proportion. The number of Algebras, Euclids, Arithmetics, and Trigonometries which appear, with the "rough ways made smooth and the crooked ways straight," make us regard the modern student with a mixture of envy and pity—envy at the possession of such broad highways to knowledge as we never dreamt of, and pity at the difficulty he must experience in choosing out of such a multitude. We cannot, moreover, help fancying that this plethora of books is not entirely without compensating disadvantages, for the very ease and tranquillity which which the student glides through the cleared forest, make him careless and inattentive of the land-marks and salient features that were so carefully noted by his more self-reliant, if less luxuriously-equipped, predecessor.

Of the twelve books on our table, we shall begin by noticing the most elementary. Among these is an instalment comprising Books I. and II. of "Euclid," by Messrs. Hall and Stevens, of Clifton College. For these revolutionary days it is remarkably orthodox; but certain changes have been introduced, very wisely as we think, where Euclid's enunciations were confusing, or the proofs were not sufficiently comprehensive, as in Propositions 8 and 26, where the identical equality of the two triangles is not usually emphasized. The authors, in their preface, enter very fully into the reasons which decided them to avoid the use of symbols at first, and also to preserve "the formal, if somewhat cumbrous, methods of Euclid," and with these reasons we in the main agree. If, however, for "a large majority of students 'Euclid' is intended to serve, not so much as a first lesson in mathematical reasoning, as the model of formal and rigid argument which most conduces to accurate and orderly thought in any field of study," we should welcome a book of geometry brought out for the use of those whose natural mathematical growth is stunted, and taste warped, by a too strict adherence to the cumbersome and often involved style of the ordinary text.

We admit the dilemma for those who wish to make "Euclid" serve the double purpose of an introduction to logic as well as geometry, but, at the same time, we are unable to see why, even for the logicians, *some* at least of the advantages of the German method cannot be introduced, such as the use of a, b, c for the sides, and α, β, γ for the angles of a triangle. A great deal of confusion arises from the use of *three* letters for an angle and *two* for a side, and the change to the simpler method would not only clear the student's mental vision, but leave the logic unimpaired.

One of the best examples of the defects arising from a rigid adhesion to the formal text is in Book I., Proposition 13. We have found many to whom this proposition in its existing form is one of the most repulsive in the book, and it has been almost touching to witness the joy evinced by a dullard on his first realizing that the obtuse angle was just as much in excess, as the acute angle was in defect of a right angle—a fact which the ordinary proof completely disguises. We do not think the alternative proof to Proposition 47 is likely to meet with much favour, and since the authors do not altogether discard alternative proofs, we should have preferred, instead, the neat alternative to Proposition 48 given in Casey.

For the purpose for which it is designed we do not hesitate to recommend the book. It is excellently printed, the construction lines being very properly faint, and the figures in all cases clearly drawn. The exercises, additional theorems, and hints to solution are also unusually well arranged, and will be truly welcome to the student who intends to go in for mathematics, as well as train his mind into logical habits.

"Algebraical Exercises," by Messrs. Hall and Knight, is, we presume, intended to be a companion and supplement to their excellent little "Elementary Algebra," which has met with such a generally good reception. While these exercises will, no doubt, be of considerable use, we think they might be improved, and rendered more widely serviceable, (1) if Part 1, devoted to the earliest rules, were extended beyond a meagre six pages—a range altogether out of proportion to what follows; and (2) if the exercises were more *gently* graduated in Part 2. For example, linear equations in three unknowns are introduced *per saltum* as early as p. 10, and all the papers after p. 6 strike us as being a good deal harder than those encountered by the Army Preliminary candidate, types of which are given on pp. 146–47. We also regret to find in the first ninety-seven pages an almost entire absence of book-work questions—a defect which is only partially made up for in the capital selection of typical public examination papers which follow. Example-grinding is no doubt an essential art, but in algebra, especially, the early parts tend to become purely mechanical, unless *real thinking* is encouraged and stimulated by rational questions on the processes employed. In a subsequent edition a few more recent University and Army papers would form a welcome addition.

Mensuration is represented by a key to Todhunter's small treatise, by the Rev. Lawrence McCarthy, of St. Peter's College, Agra. As a rule we have no great liking for keys, but if there is any country where such a key might be used with advantage, it is India. Possibly this is what prompted Prof. McCarthy to perform a labour which might fitly be termed an intellectual treadmill. We have always looked upon the "Mensuration" itself as Todhunter's least valuable work. It is full of long-winded rules which are never learnt, and the use of algebraic symbols by which all such rules could at once be rendered visible to the eye, is most curiously, and, as we think, unreasonably, avoided. The same spirit characterizes the key. Everything is worked out at full length with needless repetitions of figures, especially the oft-recurring 3·1416, which we have counted no less than twenty-nine and thirty-four times respectively on two pages chosen at random. Surely the symbol π might have been substituted with advantage here. Barring such defects, the work appears to have been well done, and will doubtless be of use, more especially to those who are unable to get tutorial assistance.

An "Explanatory Arithmetic," by Mr. G. E. Spickernell, which has reached a third edition, does not strike us as any improvement on existing treatises. Brevity, which is one of the points aimed at, is certainly secured, but at the expense of both elegance and lucidity. The rules read like excised telegrams, and are liable to be misconstrued in much the same way. Thus, to take an example of the telegram purporting to explain compound subtraction: "Take *like from like*; and whenever it is necessary, in order to make subtraction possible"; and a longer one for the subtraction of fractions runs thus: "Reduce minuend and subtrahend to equivalent fractions having their least common denominator; and then, having like parts of integers, take less number from greater, and write in figures, under remaining parts, their name." Similar highly cacophonous and ambiguous paragraphs are to be found scattered through the book, and give one the impression that they will frequently necessitate as much explanation as the principles they are intended to embody. Occasionally the author employs a definition which is palpably partial, thus: "When an integer or whole thing is divided into a number of *equal* parts, those parts are called fractions."

The entire book strikes us as being of the empirical cramming style, as opposed to the rational and scientific style so well exemplified in Brook Smith's treatise and the smaller one by Lock, in which rules are avoided as much as possible. On the other hand, it contains copious and very well assorted collections of examples and examination papers, with answers which can be readily removed from it if desired. These might be used with advantage, and the teacher, if a good one, could translate and expand the telegrams into a more rational and elegant form, or, still better, do without them.

Trigonometry, plane and spherical, is represented by two books—one, comprising the elements of both subjects, chiefly for the use of junior naval officers, by H. B. Goodwin, Naval Instructor; while the other is Part 2 of a "Treatise on Higher Spherical Trigonometry and Geometry," by Messrs. McClelland and Preston, of Dublin. Mr. Goodwin's work is intended to give, in one volume, the course usually required for an acting sub-lieutenant—which heretofore he has had to pick out of a variety of elementary works—and appears to admirably fulfil its author's intention. It is marked by simplicity of treatment, the avoidance of cumbrous rules, those bugbears of our ancient text-books, and a separation of the subject into distinct parts, each of which is complete in itself.

Messrs. McClelland and Preston's book is a new departure, in so far as, with the exception of the well-known treatise of Mulcahy, it is the first time that spherical geometry, as distinct from trigonometry, has been seriously put into text-book form. The authors are to be congratulated on their bold, clear, and systematic treatment of this too-much-neglected and really useful branch of mathematics. The work throughout is characterized by lucidity and originality of treatment, and is subdivided into complete chapters. Spherical and stereographic projection are also carefully explained, and their power as methods amply exhibited.

We cannot help thinking that both spherical trigonometry and geometry are far too much neglected in our educational curricula. In consequence, it is astonishing what errors are committed when even the simplest properties of a spherical surface are in question. The curvature of the earth is realized by few, and some who ought to know better have not yet grasped the fact that the latitude of Cairo approximately bisects the area of the northern hemisphere. Nothing but polar projections, or, better still, globes themselves, will ever correct the false impressions which we get from that terrible flat-ruled distortion entitled "Mercator's projection," from which all approach to curvature has been so carefully extracted.

The theory of the trade-winds, moreover, which has survived up to date in some of the text-books, takes no account of the shortening of the radius in considering the gain in eastward motion by the transference of the air at relative rest on the equator to higher latitudes. Thus, according to Loomis's "Meteorology," the gain is simply found by subtracting the linear velocity at the higher latitude from that at the equator; whereas when the shortened radius is considered, it amounts, in latitude 60°, to 1554 instead of 518 miles per hour, and at the Pole itself to ∞ instead of 1036 miles per hour. These are only a few of the most patent errors which arise from a neglect of spherical principles, and might be multiplied almost indefinitely.

"Hints for the Solution of Problems in Solid Geometry," by Dr. Percival Frost, is a book which cannot fail to be of great value to the student of this difficult but important branch of mathematics. Mathematical solutions have little analogy to, and, except in elementary works, none of the disadvantages of, classical cribs. In the present case, the execution of Dr. Frost's truly laborious work has been attended by an unexpected advantage, in leading to the discovery of certain errors and omissions in the statement of the problems themselves, which might otherwise have escaped notice. We heartily welcome Dr. Frost's hints, and trust they may receive the attention they so fully deserve.

While some branches of elementary mathematics are already in danger of being congested by a plethora of text-books, statics and dynamics seem to us to still pre-

sent an open field for the writers of really able didactic treatises. For those who have reached the Elysian fields of the calculus, no better book can be recommended than Prof. Minchin's admirable work; while for those who have not yet reached that stage, and perhaps never intend to, the "Elementary Statics" by Mr. John Greaves, which is written much on the same lines, can be unreservedly recommended. The science of statics, like everything else, has been obliged to *move* with the times, and Mr. Greaves, following the modern views, prefers to consider it as merely a particular case of the science of dynamics, and to base it upon the laws of motion. Thus, instead of the familiar proof of the parallelogram of forces on the principle of transmissibility of force, he deduces it solely by the aid of the parallelogram of velocities, from which, together with the third law of motion, the conditions of equilibrium are obtained more readily, and, in the author's opinion, more clearly, than usual. This expectation can only be tested by actual experience. Meanwhile we would recommend that, in a reprint of the book, the more salient propositions and results should be rendered more emphatic and conspicuous by being placed either in italics or large type. In their present form and position the plums are too disguised to be readily picked out. The work is characterized by thoroughness, and by a large number of worked-out examples illustrated by excellent figures, the material lines being very properly distinguished from the geometrical and force lines by thicker type. The free use made by the author of the purely geometrical method for solving some statical problems is elegant, but occasionally leads to a neglect of the statical or primary limitations under which they are stated. An example of this occurs on p. 86, where it is required to find the greatest inclination to the horizon at which a uniform rod can rest partly within and *partly without* a fixed smooth hemispherical bowl. The condition assumed for the maximum inclination leaves *no part* of the rod outside the bowl, which clearly violates the latter part of the question.

Machines are deferred to the last chapter in the book, presumably because some of the principles, such as virtual work, are dealt with in preceding chapters; but we think they might be advantageously introduced, at all events in a preliminary way, much earlier, since their consideration not only enlivens the otherwise dry discussion of abstract principles, but gives concrete expression to their reception. We are glad to see that the merits of this excellent little book are recognized by the authorities of the Mason Science College, who recommend it for one of their courses.

At the threshold of the higher mathematics we find two books on "Differential Calculus," which, though rivals, will, we trust, often be found in company, since each possesses certain merits and characteristics which distinguish it from the other. One is the well-known and excellent treatise by Prof. Benjamin Williamson, F.R.S., which has now reached a sixth edition. In this edition, besides careful revision, a short discussion is added on the elementary properties of solid and spherical harmonics, which are so frequently employed in the higher developments of electrical and optical theories. As a former edition of the book has been fully noticed in NATURE, we need only indorse the opinion then put forward, that it is one of the best treatises on the subject in our language. The other work, by Mr. J. Edwards, formerly Fellow of Sidney-Sussex College, Cambridge, is very different in style, and more elementary, in so far as it is, according to the author's design, "unencumbered by such parts of the subject as are not usually read in Colleges and schools." Compared with Prof. Williamson's treatise, it is distinctly more geometrical in method, and in this and some other points, such as large type, beautifully-drawn figures, an unusually full and systematic account of curve-tracing and the properties of curves, which, contrary to the usual custom, *precede* maxima and minima, it is more suited to the wants of the average student as a preliminary course of reading. Some of the geometrical illustrations, such as those of the compressed form of Taylor's theorem, $\phi(x + h) = \phi(x) + h\phi'(x + \theta h)$, and $Dz = \frac{dz}{dx}dx + \frac{dz}{dy}dy$, are very elegant, and help to keep alive the real meaning of differential symbols, which a too exclusive attention to algebraic analysis tends to annihilate. Symmetry and brevity have both been evidently studied, and a good example of this may be seen on p. 271, where the radius of curvature for an implicit function of x and y is deduced. If this be compared with the analogous method on p. 290 of Williamson's book, the difference in the style will be manifest. Regarding the two books together, we should advise a student to begin with Edwards, and then proceed with Williamson. Nothing in the former work need be omitted at a first reading, after which he may plunge fearlessly into the more complete and analytical treatise of the Dublin Professor.

Two books remain to be noticed, which lie somewhat outside the ordinary run of didactic works. One is an Algebra by Profs. Oliver, Wait, and Jones, of Cornell University, U.S. This, though originally intended as a text-book for their own students, seems, in the course of construction, to have developed into a work which, while it might be found really useful as a book of reference to teachers and the rare youth who *cultivates* mathematics, is quite unsuited to the ordinary student.

In some respects it appears to be an effort to regard algebra from the modern point of view as the science of finite operations, and to present it in the form of "a stepping-stone to the higher analysis," and there is much that is commendable from this point of view in the exposition of incommensurables, limits, imaginaries, derivatives, and graphic representation of equations, as also in the introduction of some fresh symbols, such as the Gaussian sign of congruence, $\equiv$, and $\gtrdot$ $\lessdot$ for smaller than and greater than in the sense of size only. The use of the signs $+ -$ as left-hand indices to indicate absolutely positive and negative quantities is also an improvement, and renders it easier to deal with negative and directional quantities. For English didactic purposes, however, this book will be chiefly useful as one of reference for the teacher.

In conclusion, we must not omit to draw attention to a very handy little manual of "Practical Solid Geometry," by Major Gordon Ross, of the Royal Military Academy, Woolwich, which is particularly adapted to military students. The method of orthographic projection by

"vertical indices" receives special attention, and a section on defilade—a subject not much studied in this country—cannot fail to be of use and interest to those who study the science of war. E. D. A.

OUR BOOK SHELF.

Examples in Physics. By D. E. Jones, B.Sc., Lecturer in Physics at the University College of Wales, Aberystwyth. (London and New York: Macmillan and Co., 1888.)

So many books have been written having titles similar to if not identical with that quoted above, the only object of which seems to have been to enable students to pass certain examinations with the minimum of knowledge, that it is a comfort to turn to one against which no such charge can be made. Mr. Jones's "Examples in Physics" has not been written "up to" any Syllabus, but the author has made use of portions of the manuscript in teaching classes of students taking the intermediate science and preliminary scientific courses of the London University, and he believes it will be found useful for students who are preparing for these examinations. There can be no doubt that the book will be of great assistance in this way, owing to the large number of examples and the excellent way in which they have been graduated. In addition to the examples, of which there are more than a thousand, with occasional hints for their solution, there are short explanatory chapters and paragraphs where experience has shown that they are needed. Thus, at the beginning, the C.G.S. units are thoroughly explained, as is the method of passing from one system of units to another by means of dimensional equations. Those approximate relations which are most often made use of are shown to be true, and examples illustrating the advantage of employing them are worked out. The method of using logarithms is explained, and both on pp. 19 and 21 the reader is told that there is a table of four-place logarithms at the end of the book. There is a page on which natural sines and tangents are given to three places, but not a vestige of a logarithm is to be found.

In the chapters on dynamics, hydro-statics, heat, light, sound, electricity, and magnetism, chapters which consist essentially of examples, there are clearly-written paragraphs explaining those points that do not generally seem to be grasped by students. The answers to the questions are given at the end.

The general arrangement of the book is particularly happy; it is clearly the work of a teacher whose object is to increase the real knowledge of his students, and not merely to drive them through the ordeal of an examination.

The Constants of Nature. By Frank W. Clarke. Part I. New Edition. (Washington: Published by the Smithsonian Institution, 1888.)

This volume consists of a series of tables of specific gravities of solids and liquids, and differs from the older edition in two respects. In the first place, the tables have been revised and greatly enlarged; and, secondly, melting and boiling points have been omitted, on the ground that they are already supplied by the two volumes by Prof. Carnelley, which are specially devoted to those data. How much the tables have been enlarged may be gathered from the fact that the older edition, with a later supplement, only gave 2963 substances, whereas there are now no less than 5227 distinct substances mentioned, and 14,465 separate determinations. As the author remarks, this increase is a noteworthy indication of chemical activity.

The tables are only intended to be complete as far as artificial substances of definite constitution are concerned, but, in addition to these, many minerals find places. For each substance, the formula, specific gravities, and authorities are stated. The elements take the first place, and these are arranged in order of densities. Then follow inorganic fluorides, chlorides, bromides, iodides, oxides, sulphides, &c., the various groups of organic bodies coming last. There is a very complete index to the names of substances, without which, of course, the book would be far from complete.

The author is to be congratulated on the successful completion of an undertaking entailing such a vast amount of patient labour.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Gresham College.

I trust you will allow me space for a short note upon Prof. Lankester's article in last week's issue of NATURE (p. 1), under the above heading. I have no intention of entering into a controversy with Prof. Lankester upon matters of opinion, but I am desirous of correcting statements, made by him in that article, which are inaccurate. In point of fact, the article is based entirely upon a misapprehension as to the purpose and function of the London Society for the Extension of University Teaching, and its position with regard to Gresham College. Prof. Lankester speaks of it as a Lecture Society, and refers to the "innumerable short courses" of lectures given in different halls, Vestry Halls, and others in London. He is evidently here confusing two distinct things. The short courses in large halls are given under the People's Lectures Scheme, which is an entirely different matter, and in connection with which we never use the word "University." The courses of lectures and classes carried on by the London Society and the Universities Joint Board involve a systematic course of work extending over a full term of ten or twelve weeks. It is a part of the same great movement which is carried on by the University of Cambridge (not by a Lecture Society), and more recently also by the University of Oxford, in different parts of the country.

Those who have had an insight into the methods and the result of the working of the University Extension movement have been struck with the excellence and thoroughness of the work done. Sir James Paget, in his annual address to students at the Mansion House, last February, spoke as follows with regard to some of the syllabuses:—

"As I looked through the syllabuses of such subjects as I can estimate, I could see that the amount of teaching in each of them is enough for a good beginning for some who may intend to make that subject a chief study for their lives, and enough to form an important part in the teaching of anyone who wishes to be in the fairest sense generally well educated."

In fact, the principles which underlie the University Extension movement cannot but meet with the approval of all interested in higher education. These principles are, "first, that the amplest facilities for the best kind of higher teaching, such as the Universities provide, should be brought within the reach of the great mass of the people by means of courses of instruction, given locally at convenient times and places; and, secondly, that a teaching system, as opposed to a mere examination system, is required to meet the educational needs of the time."

In his speech at Gresham College, Mr. Goschen made no claim that "Gresham's money should be assigned to the support of the lecturers of the Society." What he did point out was that the design of Sir Thomas Gresham was to establish, in the heart of London, University teaching for busy people engaged in the City, and that the aim of the University Extension movement, whether in London or the country, was in spirit the same.

Prof. Lankester charges this Society with making an objectionable use of the word "University" in order to gain financial support. He says, "the implication is that the teaching is such as is given at the Universities, and it is an entirely false implica-

tion." This implication, which Prof. Lankester calls false, we do assuredly make in the most explicit way. We assert that the teaching is deserving of the title University teaching, and I am prepared to submit to Prof. Lankester overwhelming evidence in support of this assertion.

The definition which he gives to University teaching is one which includes all the good schools, and is in no sense diagnostic of University teaching. His first condition our lecturers completely satisfy, for they have, as a rule, been men of the highest academical position, in every way the equal of those who fill ordinary College Professorships and Lectureships.

We contend that the essential characteristic of University teaching is the *method* employed in dealing with a subject; that the teaching of the Universities is directed to the elucidation of the principles of the subject taught, and to the end of bringing all the mental faculties of the student into play, so that he may be placed on the high road to pursue his studies in their higher developments; and that an important factor in producing these results is the personal intercourse between teacher and student. We assert that the University Extension method possesses these characteristics.

Our idea is that Gresham College would best fulfil its founder's intention if it were enlarged into a great central College, with permanent Professorships and all the facilities for laboratory work; the Professors, however, teaching in the evening instead of the day, so as to provide for the needs of the class which Sir Thomas Gresham intended to benefit, and for which the London Society is, in a tentative way, attempting to make imperfect provision. R. D. ROBERTS.

Charterhouse, E.C., November 5.

I CANNOT agree with Mr. Roberts that I have written under any important misapprehension of the nature and general objects of the organization of which he is secretary. I have expressed my conviction of the excellence of the courses of lectures given through its means. I object to its profession of bringing "University" teaching into London, and to its claim to represent either the University of the future or Gresham's University of the past. The fact that the Universities of Oxford and Cambridge and London have appointed members of a Committee to arrange lectures in London does not, in my opinion, constitute those lectures as parts of the teaching of those Universities, and the suggestion that this is the case—encouraged by the use of the term "University Extension"—is, in my opinion, greatly to be regretted. It is, perhaps, difficult to be sure as to the nature of the audiences contemplated by Gresham for his Professors. But supposing that his intentions could be realized in this special point by the delivery of lectures in the evening, I am at a loss to understand what public good can be served by the introduction of a new organization into London for the purpose of giving such lectures, when there are already two public institutions—viz. King's College and University College—which are not only ready to undertake such teaching if found desirable in the future, but have actually carried on such teaching in the past. The Professors of King's and University Colleges are University graduates, they are provided with laboratories and libraries and lecture-rooms, they have numbered among them some of the most distinguished scholars and *savants* of the day, and they have produced both trained investigators and large additions to existing knowledge. They only require additional endowment and public sympathy to fulfil in every respect the ideal of a true University in and for London. Yet a certain number of gentlemen connected with Oxford and Cambridge have persuaded those Universities to nominate a Committee called a Joint Board to kindly undertake the introduction of "University" teaching into London. I cannot believe myself that this new body, competing for the support of Londoners as representing the great educational want of London, viz. a real University, will fail to do harm by dividing the support which London can give to University institutions. I cannot suppose—after observation of their proceedings—that those who form the active body of the London Society for the Extension of University Teaching are as anxious to promote a true University in London as they are to find employment for their lecturers. This is quite natural, and, if admitted, is not otherwise than creditable; but the assertion of a claim to be representatives of University teaching in London on the part of these gentlemen is not so creditable.

November 6. E. RAY LANKESTER.

The Barbary Ape in Algeria.

IT may interest your readers to know that monkeys are still to be found wild at a place within three days' journey of London, and easily accessible to the most unenterprising traveller. Yesterday, in company with my son, I drove up the gorge of the Chifa, on the excellent main road between this place and Mediah. We halted at the spot where the appropriately named "*Ruisseau des Singes*" falls into the Chifa on its left bank, and ascended the narrow side-valley on foot. Its steep slopes are densely covered with brushwood, intermixed with a few oaks and stunted junipers. We had not proceeded more than ten minutes from the main road before we heard the chatter of a Barbary ape on the bank above us, and saw him scrambling along the rocks. Shortly afterwards, a fine large male of the same species was kind enough to mount a juniper-tree on the opposite side of the gorge to that on which we were seated, and exhibited himself to our gaze for at least fifteen minutes. His various attitudes were distinctly observable through a pair of opera-glasses, and we calculated his distance from us as not more than 400 yards in a straight line. A third ape was subsequently met with farther up the gorge, at a much nearer distance, but did not wait to be looked at.

I had previously seen Barbary apes on the Rock of Gibraltar, but they are there in a semi-protected condition, and perhaps introduced. In the gorge of the Chifa they are quite in a "state of nature," and in their native wilds. P. L. SCLATER.

Hôtel d'Orient, Blidah, Algeria, October 29.

Are there Negritos in Celebes?

PROF. FLOWER, in his interesting lecture on "The Pygmy Races of Men" (Journ. Anthr. Inst. vol. xviii. p. 82, 1888, and NATURE, vol. xxxviii. p. 67), after having spoken of the Negritos in the Philippines, says, apparently on the authority of Quatrefages: "As the islands of these eastern seas have become better known, further discoveries of the existence of a small Negroid population have been made in Formosa, in the interior of Borneo, Sandalwood Island (Sumba), Xulla, Bouron, Ceram, Flores, Solor, Lomblem, Pantar, Ombay, the eastern peninsula of Celebes, &c."

Without discussing here the foundation of this whole statement, I only beg to remark that in my opinion no Negritos or the like exist in the eastern peninsula of Celebes, or in the Island of Celebes at all.

Already in the year 1876, in a lecture, "Die Minahassa auf Celebes" (p. 29, note 11), I said:—"Prof. Gerland places Papuans, in the map of Waitz's 'Anthropologie der Naturvölker' (vol. v. part 1, Malays), in the eastern peninsula of Celebes, but I could not find in the letterpress of the work, on whose authority he makes this entry. It was this very note of Gerland, which induced me, when on the spot (in the year 1871), to search after them, but I did not succeed in discovering the slightest positive proof for such an assertion." And (*l.c.* p. 8) "In Celebes . . . no autochthonic Papuan element has been discovered." Neither has Dr. Riedel, the special and foremost investigator of the whole island, obtained any trace of Celebesian Negritos. I am therefore of opinion that Celebes at least (if not many more—perhaps all —of the quoted islands) ought to be omitted from the list.

As to the occurrence of Negritos in the Philippine Islands, I only spoke of them as existing in Luzon (as generally known), in Panay, Cebu, and Negros (see *Zeitschrift für Ethnologie*, 1873, p. 90, and "Ueber die Negritos oder Aëtas der Philippinen," Dresden, 1878, p. 25). A. B. MEYER.

Royal Museum, Dresden, October 24.

Altaic Granites.

HUMBOLDT and Rose, when descending the Irtysh between Boohtarminsk and Oostkamenogorsk, saw large masses of granite lying as if poured on the ends of metamorphosed slates (S. Rose, "Reise nach. d. Ural," i. 610); an observation mentioned by Zirkel ("Petrogr.," i. 506, 1866) as a famous one in relation to the age of the Altaic granite. No subsequent traveller appears to have succeeded in repeating that observation, because nobody could rediscover the actual place, which Humboldt and Rose did not define with much precision. Ritter, however, in referring to the subject, indicates the place as lying between two rivulets—Baryshnikof and Kozlovskaya.

After some unsuccessful attempts, I at last succeeded in finding this interesting locality. It is situated some five or six miles

from Boohtarminsk, on the right bank of the river, just at the entrance into the Kozlovskee gorge, and is known among the local inhabitants under the name of Slepoy Borok (Little Blind Forest). But the illustrious travellers have made rather a blunder in defining, after only a rapid examination from the deck of an Irtyshian karbaz, the mutual relations of the rocks. A section at right angles to the stream shows that the granite lies not *on* the slates, but *in* them, and that it occurs as a main vein, with some secondary ones, all having the same strike and dip as those of the slates. The main vein is some 30 or 40 metres thick, the secondary 0·5 metre, or still less. From the river one can see only the lower limit of granite, and as the joints of this rock are nearly horizontal, whilst the bedding of slate stands almost vertical, the appearance is presented which suggested the original inference that the granite has been poured out over the ends of the slates.

My measurements gave the following results:—On the level of the current the strike of the slates varies between 9h. 45m. and 10h., dip = 82°–85° north-north-east; lower limit of granite strike, 7h. 30m., dip = 73° north-north-east; upper limit of the same, strike 8h. 45m., dip 43°–45° north-north-east. The contact of the two rocks can be observed occasionally exceedingly well. In the vicinity of the granite the slate loses all traces of fissility, and becomes a very compact rock, with abundant scales of muscovite. Generally the slates are schistose, phyllitic, and chiastolitic. Both rocks are welded together. The secondary veins of granite somewhat differ in structure from the main vein, which is of a normal fine-grained variety, with little scales of biotite. The main vein is covered with young forest, consisting of pine, birch, and aspen trees, while on the slates nothing grows but rare bushes of gooseberry, honeysuckle, some species of horse-tail, and some grasses.

The conclusion of Humboldt and Rose, that some Altaic granites are younger than local schists and slates, remains indisputable. I wish to add that they are also younger than some local greenstones, as may be seen at Beeshbanovskee crags on the Irtysh, near Oostkamenogorsk, where a dioritic breccia is cemented with granitic matrix. A. BIALOVESKI.

Oostkamenogorsk, Western Siberia, September 20.

Rankine's Investigation of Wave Velocity.

THE investigation relating to the propagation of waves contained in chapter xv. of Maxwell's "Theory of Heat," and based on that of Rankine (pp. 530-31 of "Collected Papers") presents peculiar difficulty to most readers. "The kind of waves to which the investigation applies are those in which the motion of the parts of the substance is along straight lines parallel to the direction in which the wave is propagated, and the wave is defined to be one which is propagated with constant velocity, and the type of which is not altered during its propagation."

Two cross-sections of unit area at a fixed distance apart are conceived to travel through the substance with the velocity of the wave, inclosing between them a cylindrical space within which things are always in the same condition though the matter is continually changing. The momentum of the matter which enters through the front section in the unit of time is duly expressed, and also the momentum of the matter which escapes at the rear section. The difference of these two momenta is then equated to the difference of the pressures before and behind. The puzzle is to justify this *quasi* deduction from the second law of motion; and in connection with this puzzle, the question of sign occurs. For instance, if the momentum of the entering fluid exceeds that of the issuing fluid are we to attribute the gain of momentum to the fact that the contents of the cylinder are more strongly pushed forward behind than they are pushed backward in front? Such is the impression produced on the reader's mind by Maxwell's words: "The only way in which this momentum can be produced is by the action of the external pressures"; but it is not correct.

The momentum included between the two travelling sections is changed in two distinct ways: first, by convection—that is, by gain and loss of moving matter; secondly, by pressure before and behind. *The change from pressure must be equal and opposite to the change from convection; since, by hypothesis, the momentum included between the two sections remains always the same.*

Rankine merely says, "Then in each unit of time the difference of pressure $p_2 - p_1$ impresses on the mass the acceleration $u_2 - u_1$," and gives no explanation.

I remember being puzzled by this reasoning of Maxwell's some years ago, when I was writing Note A in Part 4 of "Deschanel," and getting over the difficulty by taking the two sections very near together; but my attention has been drawn to it afresh by the receipt of a paper by Prof. MacGregor, of Nova Scotia, in which the difficulty is pointed out, and evaded in the same manner in which I evaded it. Prof. MacGregor points out that Maxwell obtains a correct result only by help of a mistake in the algebraical work—the sign of a difference being changed in obtaining equation (7) from equation (6). This is certainly true as regards the fourth and fifth editions, which are now before me. In a later edition, Prof. MacGregor remarks, the sign of the difference is changed in equation (6), thus making the algebra right, but at the expense of making equation (6) inconsistent with what goes before it. The explanation contained in the sentence printed in italics above clears up the difficulty. J. D. EVERETT.

Belfast, November 2.

Alpine Haze.

PROF. TYNDALL'S letter in NATURE about Alpine haze induces me to say that as a non-scientific observer I have never, I think, during a residence of many years here, seen so much *local* fog or haze as this autumn.

On October 29—a perfectly clear and cloudless day here (Vevey and La Tour), with no appearance of fog, haze, or cloud, anywhere in the distance—I received a letter from Lausanne saying, "While I write (11.30) so dense a fog has suddenly come up that we fear for the boats on the lake." Other friends took a trip to Lavey les Bains. They were in perfectly clear air until a little beyond Villeneuve, when they found the whole Rhone Valley thick with fog, but on turning off at St. Maurice Station to Lavey les Bains (ten minutes' walk, and on perfectly flat ground) they again came into a quite clear atmosphere. As no fog whatever came here all day, I cannot say whether it was aqueous or not. We have both sorts here from time to time, but most commonly *dry*; this year has been rather an exception. I should say fogs had been more frequently damp than usual, and by observing the grass morning and evening I have found that there has been much more dew than is common in this locality.

Streaky hazes or "long horizontal striæ," as Prof. Tyndall calls them, have certainly been unusually prevalent this year.

La Tour de Peilz, November 4. M. C. C.

The Animals' Institute.

THE long-continued suffering of animals fatally injured in our streets, before the services of a slaughterer can be obtained, or the owner be found to give his permission, has often been referred to. Poor animals with incurable abdominal wounds, or, it may be, complete fracture of a limb, not unfrequently lie in the streets for hours before being put out of their misery. The police have no power to order their destruction until the person in charge assents, and he frequently cannot do this until his master has been communicated with. I remember one case where eight hours elapsed. I have recently found that complete absence of pain can be easily induced by subcutaneous injection of morphia, and perhaps you would allow me to publicly state that the apparatus and drug are always here at the service of the police gratuitously in cases of street accidents.

JOHN ATKINSON.

9 Kinnerton Street, Wilton Place, Knightsbridge, November 5.

N. M. PRJEVALSKY.

A TELEGRAM from Vyernyi—one of those small Russian towns which have grown of late in the outspurs of the Tian-Shan Mountains—announces the death of Prjevalsky, the bold and indefatigable explorer of the wildernesses of Central Asia In September last, immediately after having terminated the work which embodies the results of his fourth great journey to Central Asia, he started on a new journey, the fifth, thus prosecuting again what has been the aim of his life during the

last twelve years—that of reaching Lhassa in Tibet, and opening to science the lofty plateaus and highlands which separate East Turkestan from India. This time he proposed to start from Russian Turkestan, and his expedition had to be equipped at Vyernyi, on the north of Lake Issyk-kul. He arrived at Tashkend in October, and had left it on October 13 (old style?) on his way to Vyernyi, but he seems not to have reached that town, and must have died on the route, as far as we can judge from the telegram. The new expedition, which promised to be even richer in scientific results than all those which preceded it, was thus prevented. But Prjevalsky has left, in the travelling companions who remained so true to him in his adventurous journeys, a staff of young men who will certainly continue his work, and sooner or later open to science the dreary highlands which have baffled so many a bold explorer.

N. M. Prjevalsky was only in his fiftieth year, and usually enjoyed robust health. He belonged to a noble family, and was born in 1839, in the Government of Smolensk. At the age of seven he lost his father. During the early years of his life he was trained by his mother (whose maiden name was Karetnikoff), a teacher who stayed in their house, and a brother of his mother. He soon became an eager hunter, and spent all his holidays in hunting in the Smolensk forests with his uncle. This taste he retained during the rest of his life, and he frankly admitted that his first journeys in Central Asia were due as much to his passionate longing for rich hunting-grounds as to his desire to conquer for science the unknown wildernesses. Scientific interest developed more and more during and after his first Central Asian journey, when, accompanied only by three men, and possessing ridiculously small pecuniary means, he crossed the Gobi, reached Pekin, and, pushing westwards and south-westwards from the Chinese capital, explored the Ordos and the Ala-shan, and reached the Kuku-nor as well as the upper parts of the Yang-tse-kiang—the mysterious Dy-tchu of the Chinese geographers. And yet, when we saw him on his return from that wonderful journey, his eyes glittered and his face radiated chiefly when he was telling us of his achievements as a hunter and a discoverer of the ancestors of our domesticated animals—much more than when he was talking of his geographical discoveries, about which he always was, in fact, remarkably modest.

He received his first school education in the Smolensk Gymnasium, but he soon left this institution, and entered in 1855 an infantry regiment as a subaltern. Next year he became an officer, and five years later he entered the Academy of the General Staff. His love for geographical exploration had been to some extent developed by that time, and the dissertation he wrote on leaving the Academy was upon the Amur region, which was much spoken of in Russia. But he had not yet the means of satisfying his desire for travel, and he was compelled to return to his regiment and take part in the suppression of the Polish insurrection. He soon withdrew from active military service, and accepted the position of teacher of geography at a Warsaw Gymnasium, devoting his leisure hours to studies in natural history. It was only in 1867 that he was admitted into the General Staff and sent to Irkutsk, whence he immediately started for the exploration of the very little known highlands on the banks of the Usuri—the great southern tributary of the Amur. Here he found a wide field for exploration and hunting, and wrote a book on the Usuri region (published in 1869), partly of an ethnographical character. The Geographical Society awarded him for this book only a small silver medal; and, when Prjevalsky applied for means to enable him to explore Southern Mongolia, the Society was anything but generous in its response. Had it not been for his own small economies—he always lived a very simple life—and for the help he received from the then Russian Ambassador at Pekin (M. Vlangalli), himself an explorer of Mongolia, Prjevalsky could hardly have started on that remarkable journey. When he began the exploration of the land of the Tangutes, he possessed only 178 roubles (about £25); and when he reached, with his three companions, the sources of the Yang-tse-kiang, after having crossed the province of Han-su, the Tsaidam, and part of Northern Tibet, he had only 10 roubles left, and his camels were quite exhausted. The whole expedition, which lasted thirty-four months (November 1870 to September 1873), had cost only 6000 roubles; yet this undoubtedly was the most remarkable journey that had been made in Asia in the nineteenth century. Prjevalsky proved that, for resolute and enduring men, travelling on the Central Asian plateaus was much easier than had been supposed. He twice crossed the Gobi, reached the Kuku-nor, penetrated as far south-west as the spot where the Yang-tse-kiang rises from the confluence of the Mur-usu and the Nantchitai River, and returned with exceedingly rich zoological and botanical collections, after having travelled no less than 7320 miles across formerly quite unknown deserts and highlands. The work in which he embodied the results of that wonderful journey, "Mongolia and the Land of the Tangutes," was immediately translated into all civilized languages. The Russian Geographical Society hastened to present him with its great Constantine Medal, and most of the Geographical Societies all over Europe congratulated him on his discoveries, and awarded him medals, honorary diplomas, and the like.

Prjevalsky, in the meantime, was trying to find the means for continuing his explorations; but it was only in 1876 that he succeeded in obtaining from the Ministry of War the 25,000 roubles which were necessary to enable him to push as far as Lob-nor. His aim was not only to rediscover the basin of the Tarim and the great lake of East Turkestan, which had not been visited by any European from the time of Marco Polo; he desired to cross East Turkestan and the northern plateaus of Tibet, and to reach Lhassa. This time he started from Turkestan, and, following the upper part of the Ili River (the Kunges), he reached Kurla in East Turkestan, whence he crossed the desert and reached the Lob-nor. The great lake was thus rediscovered. But it was impossible to reach Lhassa by this route, and Prjevalsky returned to Kulja, and thence to the Russian post Zaisan. His aim was to penetrate into Tibet *viâ* Hami, the Tsaidam, and the sources of the Blue River. So he started again, from Zaisan to Gutchen. Unhappily, the skin disease of the steppes (*pruritis scroti*) overtook him, and he was compelled to return from Gutchen. Still, next March, he was again on his way to Lhassa, when the frontier authorities ordered him to postpone his expedition. He then returned to St. Petersburg.

The Lob-nor journey was made in 1877, and although only eleven years have elapsed since, it is almost impossible now to realize the imperfection of our knowledge of Central Asia at that time. When it became known that Prjevalsky had visited the Lob-nor, Baron Richthofen contested the fact, and maintained that the lake which receives the Tarim must be situated further north and due east from the mouth of the Ughen-daria; while now Lob-nor is perfectly well known. As to the natural history collections which were brought in from this second journey, they were even more valuable than those gathered during the first journey. They gave us a clear insight into the flora and fauna of those parts of East Turkestan; while the barometrical measurements enabled us to form, for the first time, a correct idea as to the characters of the Tarim depression of the great Central Asian plateau. It was also from this journey that Prjevalsky brought the wild camel—the ancestor of the domesticated species.

As soon as he was back at St. Petersburg, Prjevalsky hastened to prepare for a new journey; and after having written a short account of his Lob-nor journey,

"From Kulja, across the Tian-Shan, to Lob-nor," he left the Russian capital for Zaisan, and began his third journey, the most remarkable of all. He soon reached Barkul and Hami, the two Turkestan oases which were almost less known than some parts of the moon. He crossed the Western Gobi, and reached a spot, Dzun-zasak, in South Tsaidam, at the foot of the highlands which separate Mongolia from Tibet. Thence he went south, in order to reach the longed-for Tibetan city of Lhassa. The journey in the highlands which border the great plateau on the north-east was exceedingly difficult. Ridges, 16,000 feet high in their lowest parts (one of them was named after Marco Polo), separated from one another by deep valleys, the bottoms of which are 13,000 and 15,000 feet above the level of the sea, had to be crossed; and when the expedition reached the upper parts of the Blue River, it was brought by the guide to quite impracticable highlands, and had to find its way amidst the barren mountains, peopled by Tangutes, whose attacks had to be repulsed by force. Nevertheless, Prjevalsky crossed the highlands, and had already reached, under the 32nd degree of latitude, the great valley of the Tibetan river Khara-usu, whence the route to Lhassa was relatively easy; but here a new obstacle rose before him. The Dalai-lama had sent officials, who declared to Prjevalsky that the Tibetan nation would not allow Russians to enter the capital of the great chief of the Buddhist religion. The expedition was thus compelled to return; and so it did, re-crossing the same highlands in the midst of the winter. Having returned to the Ala-shan town Sinin, Prjevalsky did not like to go back to Russia without having visited the Hoang-ho, which makes a great bend to the north in the neighbourhood of Kuku-nor. He reached, in fact, the great river of China at Guidui, crossed it, and explored it for some 200 miles, and only then returned to Kiakhta, after having travelled about 14,700 miles, half of which stretch was surveyed, and bringing in more than 4500 specimens of mammals, birds, and fishes, 6000 insects, and many thousands of plants. The most remarkable "find" was, however, the wild horse—the ancestor of our present horse—which inhabited Russia and Poland some two hundred years ago, and has been described by the late I. Polyakoff under the name of *Equus przewalskii* (*Izvestia Russ. Geog. Soc.*, 1881). It is hardly necessary to say that this remarkable journey produced the greatest impression on the scientific world. The Russian Geographical Society elected Prjevalsky an honorary member; the city of St. Petersburg offered him its honorary citizenship, and many scientific bodies bestowed on him all kinds of distinctions. The general results of this journey were embodied in a work entitled "Third Journey to Central Asia," which also has been translated into many European languages.

As soon as the publication of this work was ready, Prjevalsky started again, in November 1883, on a new journey, again proposing to visit Tibet. This time he started from Kiakhta, crossed the Gobi in the winter, and soon reached the spot, Dzun-zasak, whence he intended to start for the exploration of the highlands of North-Eastern Tibet. But all kinds of misfortunes attended him. The expedition, freely provided with money, already numbered twenty-one men, and so it could not move with less than fifty camels and several horses. It was found very difficult to obtain such a number of animals from the poverty-stricken populations of South Tsaidam; and Prjevalsky, usually so mild in his relations with the natives, resorted to violence. The animals he thus secured proved to be quite unfit for journeys across the high ridges which fill up the space in the south of Dzun-zasak; and it seems most probable that by taking a route due south from that point, instead of proceeding south-westwards as he did during his third journey, Prjevalski committed an error. Not taking into account the north-eastern direction of the ridges, he had to cross the numerous ridges of the Upper Hoang-ho, instead of availing himself of the depressions having a south-western direction, which permitted him to reach the Khara-usu in 1880 without serious difficulty.

It is true that, by taking a southern direction, he reached the two great lakes Jirin and Orin, through which the Upper Hoang-ho flows, and that he thus solved one of the problems of the geography of Asia. But when he went further south, he had to cross such a succession of wild highlands of an Alpine character, that his camels were soon disabled; and when he reached the Dy-tchu, or Upper Yang-tse-kiang, some 120 miles to the east of the spot he visited in 1872, he found it impossible either to cross it or to follow the river downwards. He was obliged to return, and on his way back he even could not fully explore the lakes Jiriu and Orin, because the Tangutes, gathering in hundreds, violently attacked the caravan, and were repulsed only after having lost a great number of their warriors.

Having returned to Dzun-zasak, Prjevalsky went north-westwards along the foot of the ridges which separate Mongolia from Tibet, and, when at the lake Gas, he made a winter excursion into the highlands. This excursion enabled him to get a clear idea as to the series of parallel ridges which separate the Tsaidam from the higher terrace of plateaus of North-Eastern Tibet. Moreover, instead of returning from Lob-nor by his usual route, he pushed westwards into East Turkestan, as far as Khotan, and returned to Russian Turkestan *viâ* Aksu, thus covering nearly the same ground as that visited at the same time by Mr. Carey.

Years and years will pass before all the specimens of plants and animals brought in from his four journeys can be fully described. Maximowicz's description of Central Asian plants, now being printed by instalments in the Bulletin of the Moscow Society of Naturalists, already gives some idea of the richness of Prjevalsky's collections, which represent a total of 700 specimens of mammals, 5000 of birds, 1200 of reptiles and amphibia, 800 of fishes, 2000 mollusks, 10,000 insects, and from 15,000 to 16,000 plants. All the zoological specimens are in the St. Petersburg Academy of Sciences, the botanical specimens at the St. Petersburg Botanical Garden, the geological collections at the St. Petersburg University, and special funds have been granted by the Government for the publication of the scientific results of these journeys as soon as the necessary work has been done by the specialists.

The volume embodying the general results of Prjevalsky's fourth journey, and entitled, "From Kiakhta to the Sources of the Yellow River, Northern Tibet; and the Journey from Lob-nor through the basin of the Tarim," reached London only a few weeks ago, and the present writer was preparing an account of it when the sad news reached us from Vyernyi. Although less striking than his previous books, so far as geographical discovery is concerned, this work may be even more important for the light it throws on the nature of a wide unknown country. It presents also the clearest view of the traveller himself, and affords a clue to the causes of his success.

In a chapter devoted to the ways and means of travelling in Central Asia, Prjevalsky gives detailed instructions as to how an expedition ought to be organized, and when speaking of the traveller himself he writes:—"As to the person who will have before him the beautiful task of scientifically exploring new regions, his task will not be easy. The explorer will have to pay for the smallest discoveries by plenty of suffering, physical and moral. He must be strong physically and morally. Flourishing health, strong muscles, and still better an athletic complexion, on the one side, and strong character, energy, and resoluteness, on the other—such are the features which best guarantee success." And, after mentioning the necessity

of general scientific knowledge, and of special knowledge in, at least, some one branch, as well as the necessity of a real passion for travelling, Prjevalsky adds :—"Moreover, he must be an excellent shooter, and, still better, a passionate hunter. He must not despise any hard manual work, as, for instance, the saddling of horses and camels, the packing of luggage, and so on—in short, he must never be a 'white-handed' person ; he must not have habits of luxury ; and he must have a pleasant, lenient character, which will soon acquire for him the friendship of his travelling companions." In these sentences he characterized himself. To renounce, if necessary, every comfort ; to live the life of the other members of the expedition, without any distinction between the scientific staff and the simplest soldiers or Cossacks ; to sleep in the same tent, to eat the same food, and to do the same work as the rest—such were Prjevalsky's rules. We must add also that, especially during his first two journeys, his relations with the natives were of the most friendly character. He carefully avoided any conflict with them ; and when it happened once, during his first journey, that the natives were hostile to him, and this hostility might have ended in an armed conflict, he preferred to win their respect by the following stratagem. He and his three men—all four admirable sharp-shooters—opened a fire from their breech-loading rifles upon the carcass of a horse, from a great distance. In two minutes they had discharged thirty bullets each, and they advised the Mongols to see if any bullet had touched the carcass. The Mongols rushed, of course, to the carcass, and, to their great astonishment, after hard work with their knives, discovered most of the 120 bullets in it. They did not fail, after this, to treat their visitors properly.

It is impossible to mention Prjevalsky's name without being reminded of his travelling companions. He himself so often expressed his gratitude to them, and he always wrote with so much sympathy about their common experiences, that we shall only be carrying out his wish in stating that Lieut. Pyevtsoff during Prjevalsky's first two journeys, Lieut. Roborovsky in the last two journeys, and M. Kozloff during the fourth, have their full share in what Prjevalsky modestly described as his "scientific reconnoitrings" in Central Asia. Their portraits, as well as his own, are given in his last work. P. K.

SMOKE IN RELATION TO FOGS IN LONDON.[1]

LONDON fogs are produced by the mechanical combination of particles of water with particles of coal or soot, and require for their fullest development the following conditions : a still air, a temperature lowest at or near the ground in comparison with an elevation of some hundreds of feet, saturation or partial saturation of the air within a moderate distance of the ground, absence of clouds overhead, and free radiation into space. The artificial darkness and peculiar colouring occur with greatest effect at times when a very large quantity of coal is being burnt in domestic fireplaces, and cannot as a rule prevail during the night between 10 p.m. and 5 a.m., or to any great degree in warm summer weather. The early hours of summer mornings are the only ones in which clear views of the whole city are possible. Next in clearness come fine Sunday afternoons in summer, when fires are allowed to go down. The hours of greatest density are those following the time of greatest cold on the earth's surface and of the lighting of large numbers of kitchen and other fires. Thus about 8 to 10 a.m. is frequently the period of thickest and darkest fogs. It may be noted that on Sundays, when factory fires are inoperative, fogs in winter have been densest : on one Christmas Day there was absolute darkness during the whole day, thus showing the dependence of light-absorbing matter on kitchen and domestic fires. Many distinct conditions may alter the time of maximum density.

[1] Abstract of an Address delivered by the Hon. F. A. R. Russell, on March 1, 1888, under the auspices of the Smoke Abatement Institution.

The formation of a London fog appears to take place as follows. An ordinary thick white fog covers the city, say at 6 a.m. ; about a million fires are lighted soon after this hour, and the atmosphere becomes charged with enormous volumes of smoke—that is, the gases of combustion bearing carbonaceous particles. Now, these particles, as soon as they are cooled to the temperature of the air, or below it, begin to attach to themselves the water spherules already present and visible, and vapour may also be condensed on the particles. A thick layer of these united particles prevents light from penetrating it, and a very small quantity of finely divided carbon may stop the bright sunshine altogether, like the film of soot on a smoked glass. The invariable redness of the sun through smoke seems to show that the majority of particles are comparable in diameter to the length of a wave of blue light. Smoke prevents the warmth of the oblique sunshine from reaching and evaporating the white fog near the ground, and the white fog continues to radiate towards space and towards the ground, if colder than itself, without receiving compensation from the solar rays. A difference of 10° has occasionally been noted between thermometers at 4 feet and 100 feet above the ground, the upper one always being the warmest in fogs. Carbon is a good radiator, and tends from this cause to keep itself cold by radiation into space, and thus to accumulate vapour from the air, like the dewy surface of the earth. The importance of a clear sky and a dry upper air in promoting fogs in this respect is obvious.

It has been supposed, quite erroneously as I believe, that, as even without any visible smoke an enormous quantity of fine invisible dust exists in the London atmosphere, the abolition of coal smoke would fail to give us freedom from dark fogs. Proof is altogether wanting that ordinary invisible dust in cities or plains is of a kind to create an abnormal amount of fog, or to produce those dismal obfuscations of which tarry carbon is capable. Paris, as long as it burnt wood and charcoal, was free from idiosyncratic fogs ; so are the wood and anthracite-burning cities of the United States ; and so are the towns of South Wales, where anthracite is the common fuel. If London were to cease using fuel in the solid form, it would be as free from fog as the surrounding country.

The accumulation which produces the worst and most dangerous fogs in London cannot, as a rule, proceed for many hours without disturbances arising which tend to reduce their importance. In winter the warmth of the air exceeds by 2° or 3° that of the surrounding country, consequently an upward current is started, which rises to some altitude, and then flows away, bearing with it a stream of murky cloud ; a circulation of air consequently takes place in the lower strata. If, however, the cold of the lower layers greatly surpasses that of the strata some hundreds of feet higher, and if the sun dissipates the fog in the surrounding country, thus making the environs warmer than London itself, the black fog may very likely remain on the town all day. For this reason, on a fine cold still morning, with a bright sun, and temperature near the dew-point, persons arriving from the country are pretty sure to find a black fog in town between 10 and 12 a.m. The finest winter days are nearly always very bad ones in London, unless there be any wind between the surface and an altitude of 1000 feet, or the dryness be unusual for the time of year.

When the air is very dry near the surface, no dense fog is formed in London, and when very wet, streaming with fog, in the country, little fog occurs in London. The dry warm surfaces of the houses themselves, and the elevation of temperature above the dew-point, prevents wet fogs from reaching anything like the density they attain in the

country. A wet fog disappears under cover, showing its causation by the radiation of its particles towards colder surfaces or space, as well as by mixture of differing air-currents. A dry fog persists to some degree in a warm room, showing it to be largely composed of carbonaceous particles of visible magnitude. There is nothing in the geographical position of London to make it more foggy than many other parts of the country, and, owing to the conditions just mentioned, it would probably rejoice in a clearer air, on the whole, than that of the surrounding districts if ordinary coal were superseded by anthracite and gaseous and liquid fuel.

From the daily tables of weather of the Meteorological Office for 1872, 1873, 1875, 1876, 1877, and 1882, which happened to be in my possession, I have obtained the following results, showing the prevalence of fog at different stations at 8 a m.

The first column (*b*) shows the number of days per cent. of blue sky or free from cloud at 8 a.m., and the second column (*f*) the number of days per cent. when fog more or less prevailed at that hour.

	b.	*f.*
Aberdeen	22	2
Valencia	10·1	2·4
Hurst Castle	13·7	3·2
Leith	11	5·3
Dover	27·9	6
Holyhead	13·2	6·2
Liverpool	12·4	6·6
Pembroke	12	8·5
Scilly	2	10
Oxford	10·4	10·5
Yarmouth	14·5	12·2
London	8	13·5

Aberdeen and Dover have by far the largest number of fine mornings, Aberdeen, Valencia, and Hurst Castle the smallest number of fogs.

The following list, from data of the second order stations of the Royal Meteorological Society, shows the percentage of fogs—that is, the number of days with fog—for eleven stations, during the years October 1879 to September 1882.

	Days of fog.	Notes.
Carmarthen	4·5	No observations in 1880.
Southbourne	4·8	
Ramsgate	5	
Cheltenham	7	
Eastbourne	7·9	Only two years' observations.
Llandudno	8 8	
Babbacombe	14·6	
Hereford	19·1	Only one year's observations.
Croydon	25·9	
Strathfield Turgis	26	
Norwood	34·5	

The following table gives the results of the registration of bright sunshine by glass recorders at seven places in the South of England. The figures give the number of hours of bright sunshine recorded in the four years, 1883, 1884, 1885, and 1886. In the cases of St. Lawrence, Isle of Wight, and St. Leonard's, where data for only two years existed, the result is arrived at by multiplying the value in each case by two. Eastbourne only recorded in 1886, and the result for this year has been multiplied by four. The second column gives the number of hours of bright sunshine in November and December 1885, and January and February 1886.

City of London	3925	62
Kew	5713	222
Greenwich	4845	157
Eastbourne	6660	300
St. Lawrence, I.W.	6774	316
Southbourne	6115	
St. Leonard's	6880	

This absence of light must tell decidedly on the vital force of the community, taken as a whole, and even if we had no dense fogs it would be worth cleansing our atmosphere to get the proper amount of sunshine.

In the great fogs of 1880, the death-rate of London rose from 27·1 for the week ending January 24 to 48·1 for the week ending February 7, which was the period of thickest fog. The death-rate for nineteen provincial towns in this last week was 26·3. At Croydon the rate only rose from 35 to 36. In this period of three weeks from January 24 to February 14, the excess of deaths over the average in London was 2994. Probably ten times as many were ill from the combined effects of smoke and cold. In the week ending February 7, the deaths from whooping-cough were unprecedentedly numerous, 248, and from bronchitis, 1223. Clearly, persons liable to bronchial attacks should if possible keep out of London during winter anticyclones.

The moral reaction of this atmosphere is well worthy of consideration. If smoke were got rid of, there would be a great revival of plant vigour and human gaiety, the housewives who now give up in despair the attempt to keep their houses bright and clean would no longer lose heart, the dull brick walls would begin to deck themselves with colour and ornament, the grime which seems to pervade everything would disappear, and sky and earth would appear in their natural brilliancy.

As the result of a computation taking into account the damage to buildings, furniture, ceilings, wall-papers, works of art of all kinds, the extra washing, and consequent wear and tear, for 4,000,000 people, window-cleaning, waste of coal, extra lighting required, chimney-sweeping, loss of time by artists, &c., impairment of health, and many other items, it appears that the loss by our wasteful method of burning coal must be about £5,000,000 a year.

There are many ways by which householders may economize in the use of fuel. Among them may be mentioned, the use of hot-water pipes and coils at low pressure heated by a coke stove, improved kitcheners, anthracite, patent fuel, mineral oil, and gas. With a reduced price of gas, gas cooking-ranges ought to come into general use. Gas fires throughout a house, except perhaps in one room where an open fire might be kept up, save the following expenses: burning fuel at times when not required, labour and wear and tear in carrying coals, dirt and blackening of ceilings, &c., wood for lighting, sweeping of chimneys, coal-scuttles, fire-irons, emery, and the very considerable amount of domestic labour now taken up by cleaning, laying, and attention generally. Wherever an open coal fire is insisted on, the various improved grates may be employed with great advantage both for economy and smokelessness. Rows of houses could probably be heated economically by hot-water or steam pipes from a boiler in a central position; but the uncertainties of our climate make independent arrangements on the whole preferable. Wasteful ranges might be subject to a tax, which the wasteful householder might be presumed to be capable of paying without inconvenience, and smoky chimneys should not be allowed to pollute the atmosphere with impunity. This would have an effect opposite to that of the tax on light, the window-tax, which vexed the last generation, for it would tend to increase the brightness of London dwellings by the admission of sunlight.

The method of heating water by the arrangement known as the "Geyser" or "Therma" has the merit of utilizing nearly the whole of the heat given off by the gas in burning. This could be employed at the top of the house, the hot water running into pipes in the rooms or on landings, and finally into a cistern in the kitchen, and here, if necessary, an ordinary boiler for heating coils in the upper part of the house or in the hall would utilize the water not yet cooled to the temperature of the air.

The abolition of smoke would certainly effect a very large saving to the community, and would add greatly to the amenity of the climate, not only of London, but of all

the adjoining counties. Thousands of acres in the environs could be acquired and turned into gardens with the savings of a single year in the perfect combustion of fuel. In times of distress a sum equal to the wages of 100,000 labourers is now thrown away in the manufacture of an artificially coloured atmosphere. Remedies in accordance with science are at hand; it only remains for society to see that they are applied.

DESICCATED HUMAN REMAINS.

SOME time ago, Signor S. Marghieri, the Mexican archæologist, while exploring the eastern side of the Sierra Madre Mountains in Mexico, at an elevation of nearly seven thousand feet, discovered and explored a hermetically sealed cave. The floor was nearly smooth, the sides rough and rugged, and the vault covered with stalactites. At the far end of the cave, which was of considerable dimensions, four mummified human bodies were found. The bodies—a full-grown male and female, and a boy and girl—were in a sitting posture, hands crossed on the breast, and knees approaching the chin, with the head inclined forward. They were all carefully enshrouded in burial garments, and accurately placed facing the rising sun. We may suppose that the elder male and female were husband and wife. They sat side by side; the elder child, a boy, was placed to the right of the father; the younger, a little girl, to the left of the mother. There was no trace of any implements, utensils, or personal effects; nor were there on the walls hieroglyphics or pictographs. The cave had been sealed by means of sun-dried, adobe bricks, and adobe paste or plaster, together with natural rocks from the mountain. So well was the work done that none but an acute observer would have noticed the artificial closure.

The bodies were brought to San Francisco, and bought by Mr. J. Z. Davis, by whom they were presented to the State Mining Bureau, in the archæological department of which they are now preserved. The following description of them is taken from a careful report drawn up by Dr. Winslow Anderson, for the Board of Trustees of the California State Mining Bureau:—

These naturally mummified bodies differ from mummies proper, in the general acceptation of the term, inasmuch as no embalming process for their preservation was used. They were desiccated in their cave sepulchre by natural elements. The dry hot atmosphere extracted all the moisture from the tissues, and the bodies literally dried up as we would dry jerk-beef, or as the Indians of to-day dry the bison (buffalo) meat which keeps for years.

There is no evidence of these bodies having undergone any preparatory process. The brain, heart, lungs, abdominal and pelvic viscera are all intact and dried to a solid consistency.

The elder male body is about five feet eight inches tall, and well proportioned. The bones are large, and he must have had an excellent physique. He probably weighed between one hundred and eighty and two hundred pounds. All the body now weighs is fourteen pounds.

The integument is well preserved, and presents the appearance of dried hide, or thick parchment, of a dark gray colour, and all that remains between it and the bones are the dried muscles, tendons, nerves, and fascia. The body is well developed, the shoulders measuring from one acromion process to the other, three hundred and ninety millimetres (about fifteen and a half inches); the hands are small, and the fingers tapering; the feet are also small, measuring two hundred and forty millimetres (about nine and a half inches), and highly arched. The phalanges of the digits are perfect, each having the normal number of bones, and the ungual appendages are well preserved and not unusually long.

The body has dried in the sitting posture, hands crossed and knees drawn towards the chin. The cheek and lips on the left side protrude. This probably occurred during the time of mummification; the moisture leaking from the interior of the brain and surrounding tissues, through the cribriform plate of the ethmoid at the anterior portion of the calvaria, through the cribriform foramina into the inferior meatus nasi, and the head being inclined toward the left, produced this bulging from the force of gravitation. Being itself in turn dried up, the mouth maintained its present shape. Short stiff hairs can be seen on the head. The eyebrows and eyelashes are also distinctly visible. A little hair can also be noticed on the upper lip, but very little beard anywhere on the face. The ears are closely pressed against the sides of the head, and only the cartilages remain. The eyes are quite perfect, and present a slight outward obliquity. The nose, originally broad, has been more flattened by the shrinking of the cartilages and the alæ nasi. The lips are stiff and solid, and the tongue is shrivelled to the consistency of cork. There is a full set of masticators in his mouth, thirty-two in number, and all quite well preserved. A few of the dentures only have the enamel worn down to the dentine. The ribs are large and well formed, indicative of a well-shaped chest. The genitalia are well preserved. On the head there has been a large growth of hair, on the face very little, and on the body scarcely any at all.

Owing to the dried integument and fascia covering the cranium, accurate measurements of the skull are well nigh impossible. The following measurements, however, have been made with as much care and accuracy as the subject permitted. The cranial measurements are as follows: circumference, 530 millimetres; length, occipito-frontal, 178 mm.; breadth, bi-bregmatic, 140 mm.; breadth of frontal, 108 mm.; height, 135 mm.; facial angle, 71°.

The sutures and wormian bones cannot be inspected. The malar bones are quite prominent and the lower maxillary and face may be classified with the group orthognathous.

A careful study of this mesocephalic head would indicate that its possessor was of more than average intelligence. The perceptives are well developed. And, although the animal passions undoubtedly predominate, there is enough veneration or religion to class it among the scaphocephalic skulls.

The elder female body is in a better state of preservation than the preceding body. From a measurement of the individual bones, she would be about five feet five inches tall, and weighed, perhaps, about one hundred and fifty to one hundred and seventy pounds. The body weighs, in its present condition, only twelve pounds. The posture, integument, body, &c., resemble the one previously described. The large, oval pelvis, and the once well developed mammæ bear unmistakable evidence of gestation. The hands and feet are small and well shaped; the foot measuring only two hundred and fifty millimetres (about eight and one half inches). On the head is a luxuriant growth of hair, which centuries have not succeeded in destroying. It is very fine in texture, of a dark brown colour, and entirely unlike any Indian hair seen to-day. A curious feature is observed in connection with the small, well-proportioned ears, both of which are perfectly preserved, and that is, in each lobe is worn, even in the stillness of death, a piece of hollow bamboo or reed, about forty millimetres in length, and ten millimetres in diameter. This was probably considered an ornament in her day. The Indians of to-day pierce the helix and antihelix of the ear, through which holes they suspend ornaments of different kinds. The single perforation in the lobe of this mummified woman's ear would indicate a custom observed by her people, similar to the customs in vogue in the more civilized countries, and are not usually observed by Indians of our own period.

The eyes are singularly perfect, presenting a slightly outward and upward obliquity of the external canthi.

The nose is also quite perfect, and inclined to be rather broad and flat than thin and protruding. The malar bones are very prominent. The lips are thin and stiff, and the tongue is dried and solid. Two central incisores and one canine of the superior maxillary are gone, and several other teeth are badly caried.

Here, again, the hair and dried integument prevent absolutely accurate cranial measurements. The skull measures: circumference, 503 millimetres; length, occipito-frontal, 166 mm.; breadth, bi-bregmatic, 128 mm.; breadth of frontal, 103 mm.; height, 132 mm.; facial angle, 69°.

This skull presents a large forehead and well-developed reasoning powers. It is very rare to find so good a head among Indian women of to-day.

The little boy seems to have been about seven years old. The little fellow had been enveloped in his burial shrouds the same as the larger bodies—hands crossed on the chest, knees doubled on the breast, and the head inclined forward. All the bodies were probably tied in this position when placed in the cave. The body is about three feet tall, and weighs now only three pounds. The same general characteristics as to skin, tissues, bones, &c., that were observed in the preceding bodies, may also be seen here. The head is well developed for a boy of his age. The hair has been broken off near the scalp. Only the cartilaginous parts of the ears remain. There is the same contour of face—flat nose, high cheek-bones, outward obliquity of the eyes, &c. The upper and lower incisores and canine of the temporary or milk teeth are gone, and the permanent set coming at their roots in the alveolar processes.

The two anterior molars of the superior maxillary are just appearing through the alveolar processes, establishing the age with tolerable accuracy at about seven years.

In circumference the skull measures 440 millimetres; length, occipito-frontal, 146 mm.; breadth, bi-bregmatic, 120 mm.; breadth of frontal, 60 mm.; height, 114 mm.; facial angle, 71°.

A considerable part of the burial shroud remains about the body yet. The major portion of it is cotton fabric, firmly secured around the body by a stronger cord, made of braided hair.

The little girl may have been about fourteen to eighteen months of age. She weighs only a pound and a half. She has been enveloped in an animal's skin, the better to protect the tender frame. Both feet are gone, and the tibiæ and fibulæ protrude through the skin. The four upper and four lower incisores, with the corresponding canine teeth, have made their appearance, showing the child to be about fourteen to eighteen months old. Otherwise the same features are noticeable in this as in the proceding figures.

It would appear that the group of four belong to one family, and that they were buried by friends, and hermetically sealed in this cave for fear of some real or imaginary foe. It may have been at the time of the Spanish invasion, or it may have been during the warlike times anterior to this date, when the Aztec confederation was warring with the Toltec people.

From their physical and mental developments the race seems to have been a superior one.

The facial features observed in these bodies are not those found in that locality now. The cranial configurations and physical appearances would rather favour Aztec lineaments than those of the Indian of to-day. The fine dark brown hair is certainly not Indian, nor do the small hands and feet bear much resemblance to the huge hands and feet we see on the Indians now living.

The fabrics found on the bodies, forming the burial shrouds, are chiefly composed of cotton, hair, hide, grasses, and the bark of willows. The cotton is twisted and coarsely woven, each thread being from a half to one millimetre in diameter. The hair is treated in like manner occasionally, although usually it is braided with three or four divisions in each cord. Frequently we find strong strands made of strips of hide covered with willow bark.

Although the weaving of this interesting people is that known as the "plain" process—that is, where the weft passes alternately under and over the threads of the warp, producing more or less open mesh cloth—yet considerable skill and ingenuity were observed in the manufacturing of their blankets, mats, and ornamental cloths, which were frequently interwoven with beads and coloured threads, presenting various designs. Grasses and straws were also woven into mats and cloths, which were of great durability. The skins of animals were also used for clothing purposes.

THE PHILIPPINE ISLANDS.

MR. WALLACE, in his great work "The Geographical Distribution of Animals," divides the Oriental or Indian region of Mr. Sclater into four sub-regions, of which Java, Sumatra, Malacca, Borneo, and the Philippine Islands form one, which he calls the Indo-Malayan. In his discussion of the Indo-Malayan sub-region Mr. Wallace recognizes several subdivisions of it, and treats of the Philippine Islands as one of the most important of these. Though acknowledging the existence of divisions of his sub-regions, he failed to give them technical names, as being at that time uncalled for.

The purpose of this paper is to show that the Philippines themselves are separated into several distinct zoological divisions, and it seems therefore necessary for their study to give technical names to the primary and secondary divisions of the already recognized sub-regions. The terms province and sub-province seem least objectionable, and will be made use of, the Philippine Islands thus forming one of the provinces of the Indo-Malayan sub-region, and the divisions of the group itself sub-provinces.

The zoological province of the Philippines is co-extensive with the political division of the same name, with perhaps the exception of the islands of Sulu and Tawi Tawi, which lie between the Philippines and Borneo, but are claimed by the Spanish.

The sub-provinces proposed are—first, the Northern Philippines, consisting of Luzon and Marinduque, and a number of other small islands about Luzon; second, Mindoro; third, the Central Philippines, made up of the islands of Panay, Negros, Guimaras, Zebu, Bohol, and Masbate; fourth, the Eastern Philippines, comprising the islands of Samar and Leyte; fifth, the Southern Philippines, embracing the great island of Mindanao, with Basilau, and perhaps Sulu; and sixth, the Western Philippines, consisting of the islands of Paragua or Palawan, and Balabac.

The geographical positions of these sub-provinces are so far fortunate, that these names show their relations to each other very closely, as may be seen by consulting a map of the archipelago.

Of the sub-provinces, the Western Philippines, made up of Paragua and Balabac, and perhaps the Calamines, is of most importance, its animal life being much more closely allied to that of Borneo than that of any other sub-province of the group. This is especially noticeable in its mammals, of which it possesses, in common with Borneo, the genera *Tragulus*, *Tupaia*, and *Manis*, which are apparently absent from the rest of the archipelago. Of Bornean genera of birds, not found elsewhere in the group, *Iora*, *Criniger*, *Polyplectron*, *Tiga*, and *Batrachostomus*, are examples. This sub-province has evidently received a large part of its fauna from North Borneo, through Balabac, at a comparatively recent date, and

since its separation, on the north, from the rest of the Philippines, so that these genera have not flowed over into Mindoro and Luzon. In addition to these apparently late arrivals from Borneo, the sub-province possesses a large number of peculiarly Philippine birds and mammals, which show it to be an integral part of the province.

The rest of the Philippines would seem to have received their Malayan fauna at another time, and by the other way of Sulu and Mindanao. They possess the mammalian genera, *Galeopithecus*, *Tarsius*, and *Cervus*, which are apparently wanting in the western sub-province, and the genera *Macacus*, *Sus*, *Viverra*, *Paradoxurus*, and *Sciurus* in common with it. Of birds, the genera *Loriculus*, *Cyclopsitta*, *Buceros*, and *Penelopides* are examples of forms which are more or less generally distributed over the archipelago outside of the western sub-province.

The grounds for dividing the Philippines east of Paragua into sub-provinces are, to a great extent, based upon species, and especially upon the existence in each of representative forms of the genera *Loriculus*, *Buceros*, *Penelopides*, *Pitta*, *Chrysocolaptes*, *Dicæum*, *Cinnyris*, &c. The hornbills form perhaps the most striking example of this distribution of representative species. Of the eleven species of hornbills obtained in the islands, the western sub-province has one, the southern three, the central two, the eastern two, Mindoro one, and the northern sub-province two, and we have found no case of a single species occupying more than one sub-province, or of more than one species of a genus in a single sub-province. The genus *Chrysocolaptes* of woodpeckers is also noticeable, each sub-province possessing its own species, with the exception of Mindoro, which lacks the genus altogether. The genus *Loriculus* of the parrots is of the same character. Of other animals than birds, the genus *Sciurus* of mammals, and *Draco*, the flying lizards, seem to have representative species in each sub-province, and the land-mollusks are probably distributed in the same way.

The above examples are a few that come to mind before a careful study of our collections has been made, and they do not by any means show all the reasons for the conclusions arrived at. These are the results rather of the general observations of five careful men who have been collecting and studying in the Philippines during the last year. During this time we have visited and collected in fifteen islands of the group, and these the largest and most important. I am satisfied that the study of our collections with the aid of the libraries and collections at home, will only strengthen the conclusions of this paper. It may be necessary to make the so-called western sub-province of more importance in the arrangement, but the non-existence in nature of exactly equivalent divisions of any kind is well recognized.

It is hoped that our work may aid in untangling some of those puzzles in which students of Philippine zoology have found themselves involved, and that it will also add considerably to the sum of knowledge concerning this, as yet, imperfectly known corner of the earth.

Manilla, July 2, 1888. J. B. Steere.

BAROMETRIC OSCILLATIONS.

THE following account of what appears to have been the passing of H.M. surveying-ship *Egeria* through the embryo of a cyclonic disturbance, has been received from Captain Aldrich, of that ship.

Admiralty, August 1. W. J. L. Wharton.

H.M.S. "Egeria," at sea, June 6, 1888.

I send the following extract from my journal, which may possibly be of interest to meteorologists:—

"*May* 31.— . . . There has been a swell from the south-west during the day. The lower clouds come from the eastward, while the upper ones are from the westward. This appears to be a common occurrence in this locality.

"♀ *June* 1.—Weather cloudy all night, and wind-force 2·3, gradually veering, till at 3.30 a.m. it was to the northward of east. Barometer rising slowly. At 6 a.m. the wind shifted to the north-east in a rain-squall; nimbus, and a generally dark appearance in the sky. At 7 a.m. the officer of the watch sent down to tell me the barometer had fallen 0·12 of an inch in the previous hour. I was about to commence dressing at the time, but, hurrying on my things, I looked at the aneroid in my fore-cabin, and found the report correct. I immediately reset the aneroid and went on deck, and although there were no signs of any forthcoming disturbance, the light sails and mainsail were taken in. At 7.20 I had the barometer again read, when it was reported to have risen nearly $\frac{1}{10}$ inch in the twenty minutes. I went down immediately, and found by the aneroid this jump had taken place. During this time there was no change in the weather, though the wind drew to the north-north-east."

Now there is no doubt whatever that the barometer went up 9/100 in twenty minutes. Of course, it cannot be known to an hour when it previously dropped ·12, as the instrument was not read between 6 a.m. and 7 a.m., and the drop may possibly have been greater even, and also *may* have taken place as suddenly as it rose afterwards. There is no doubt that some extraordinary disturbance of the atmosphere took place, though beyond the foregoing observations we neither saw nor experienced anything of it. The following are the actual readings of the mercurial barometer:—

a.m.		Inches.	Position.
6	...	30·170	Lat. 24·04 S.
7	...	30·050	Long. 179·04 W.
7.20	...	30·144	
7.30	...	30·154	
7.45	...	30·186	
8	...	30·186	
9	...	30·200	

Pelham Aldrich.

NOTES.

THE following is the list of names recommended by the President and Council of the Royal Society for election into the Council for the year 1889, at the forthcoming anniversary meeting on the 30th inst.:—President: Prof. George Gabriel Stokes. Treasurer: Dr. John Evans. Secretaries: Prof. Michael Foster and Lord Rayleigh. Foreign Secretary: Prof. Alexander William Williamson. Other Members of the Council: Prof. Henry Edward Armstrong, Henry Bowman Brady, Charles Baron Clarke, Dr. William Huggins, John Whitaker Hulke, Prof. John W. Judd, Dr. Edward Emanuel Klein, Prof. E. Ray Lankester, Prof. Herbert McLeod, Sir James Paget, Bart., William Pole, William Henry Preece, Sir Henry E. Roscoe, Dr. Edward John Routh, Prof. Arthur William Rücker, and Captain William James Lloyd Wharton, R.N.

THE Pasteur Institute, Paris, is to be opened on the 13th inst., in presence of numerous delegates of the French Academies of Science and of Medicine, and of the Medical and Scientific Faculties. President Carnot will perhaps be present.

WE regret to announce the death of the well-known geologist, Dr. Theodor Kjerulf, Professor at the University of Christiania, and Director of the Geological Survey of Norway. He died at Christiania on October 25, at the age of sixty-three. He received his appointment as Professor in 1858, and since that time has made many important contributions to geological science.

THE death is announced of Herr Johann Kriesch, Professor of Zoology and Prorector of the Royal Joseph Polytechnic at Budapest.

THE first wing of the Durham College of Science, Newcastle, was opened by the Princess Louise on Monday. The plans for the structure as a whole are very elaborate, and it is expected that the building, when completed, will be a great ornament to Newcastle. The wing just opened is about a third of the College, and has cost £23,000. The remainder will be built when the necessary funds are raised. Many of those who took part in the opening ceremony afterwards met at luncheon. Mr. John Morley, responding for the House of Commons, referred to the number of eminent men of science now in Parliament. Touching on the question how far Parliament may be expected in future to sanction expenditure for the promotion of such objects as the Durham College of Science has been founded to maintain, Mr. Morley said that the House of Commons would be willing to sanction grants from the public purse for objects of this kind in proportion to one thing, and that was to the evidence that could be brought before them that in localities an effort had been made to raise as abundant funds as these localities could provide.

H.M. SURVEYING-SHIP *Egeria*, under the command of Captain P. Aldrich, R.N., has, during a recent sounding cruise and search for reported banks to the south of the Friendly Islands, obtained two very deep soundings, of 4295 fathoms and 4430 fathoms (equal to 5 English miles) respectively; the latter in latitude 24° 37′ S., longitude 175° 8′ W.; the other about 12 miles to the southward. These depths are more than 1000 fathoms greater than any before obtained in the southern hemisphere, and are only surpassed, as far as is yet known, in three spots in the world—one off the north-east coast of Japan, of 4655 fathoms, found by the United States s.s. *Tuscarora*; one of 4475 fathoms, south of the Ladrone Islands, by the *Challenger*; and one of 4561 fathoms, north of Porto Rico, by the United States ship *Blake*. Captain Aldrich's soundings were obtained with a Lucas sounding-machine and galvanized wire. The deeper one occupied three hours, and was obtained in a considerably confused sea, a specimen of the bottom being successfully recovered. Temperature of the bottom, 33°·7 F.

IT appears from the Annual Report of the Société des Naturalistes de Moscou, which was read at its annual meeting on October 15, that the Society now has 535 members. During the past year the Society sent out MM. Zarudnyi, Litvinoff, Lorentz, Milutin, Kosmovsky, Golenkin, and Rostovtseff for the exploration of the Transcaspian region and the Caucasus, as well as for zoological and botanical explorations in several provinces of Central Russia. Besides its *Bulletin*, the Society has brought out a new instalment of its *Mémoires*.

THE courses of lectures at the Tomsk University were opened on September 13. There are already sixty-nine students, all Siberians.

NOTWITHSTANDING the considerable difficulties which have been met with in the digging of a canal to connect the Obi with the Yenisei, and the want of money for the completion of the undertaking, the work of connecting the two great arteries of navigation in Siberia is still advancing. In the summer of the present year a boat 56 feet long and 14 feet wide, taking 3½ feet of water, was drawn from the Obi into the Yenisei with a load of 40 tons of flour. The two rivers are 630 miles apart.

ON October 17, 1887, Mr. William Colenso, F.R.S., read before the Hawke's Bay Philosophical Institute a "Jubilee paper," entitled "Fifty Years Ago in New Zealand." This paper has now been published. It contains, among other interesting records, an excellent account of the introduction of the printing-press into New Zealand, and of the printing of the New Testament in the Maori language in 1837. Recalling the events of his life during his long residence in New Zealand, Mr. Colenso refers to December 25, 1835, when he met Darwin in the Bay of Islands, and spent with him "a happy long day."

THE atomic weight of tin has been redetermined by Prof. Classen and Dr. Bongartz, of Aix-la-Chapelle. Four distinct series of determinations have been made, including in all no less than forty-seven separate estimations. The accuracy of the work may be judged from the fact that the difference between the highest and lowest values obtained is no more than 0·4. The first series consisted in oxidizing pure tin to stannic oxide, and thus determining the ratio $Sn : O_2$. The purest commercial tin was taken as the starting-point, and the 0·5 per cent. of impurities removed by the following process. It was first converted to stannic chloride, $SnCl_4$, by the action of dry chlorine gas; the chloride was next fractionally distilled, and a portion eventually obtained boiling constantly at 120° C. This was diluted with water, and treated with solution of sodium sulphide until the precipitated sulphide of tin redissolved; a quantity of caustic soda solution was then added, and the liquid allowed to stand for a few days. It was subsequently submitted to electrolysis in weighed platinum dishes, upon the interior surface of which the tin was deposited as a beautiful silver-white metal. The tin obtained in this manner was exceedingly pure, and eminently suitable for use in atomic weight determinations. Weighed quantities of it were, in the first series of experiments, oxidized with redistilled nitric acid; the excess of acid was expelled upon a water-bath, and the residual stannic oxide first gently ignited over a small flame, and finally more strongly heated in a muffle furnace. The mean atomic weight derived from eleven such experiments is 118·76, a value considerably higher than the usually accepted one, 117·8, based upon Dumas's redetermination in 1858. In the second series the ratio of $Sn : Cl_4 + 2NH_4Cl$ was estimated, as given by electrolysis of the double chloride of tin and ammonium, $SnCl_4 . 2NH_4Cl$. Pure stannous chloride prepared as above was readily converted into this double salt which was obtained in fine crystals. Weighed quantities were dissolved in solution of ammonium oxalate and submitted to electrolysis, the tin being again deposited, washed, dried, and weighed. Sixteen such estimations give the mean value 118·81. The third series were precisely analogous, the double chloride of tin and potassium being employed; the mean of ten determinations affords the number 118·80. In the fourth series pure tetrabromide of tin was electrolyzed in presence of ammonium oxalate and oxalic acid, and the ratio $Sn : Br_4$ thus arrived at. The mean result of ten experiments in this series is 118·73. Finally, the mean value deduced from the whole forty-seven experiments is 118·77, or in round numbers 118·8, oxygen being taken at Stas's value, 15·96. If oxygen be 16, tin becomes slightly less than 119·1. This important metal may therefore be added to the interesting list of those whose atomic weights are probably whole numbers.

MR. G. V. HUDSON notes in the current number of the *Entomologist* that on March 7 he observed the largest assemblage of moths he has ever seen in New Zealand. They were flying round an electric light suspended from the yard-arm of the steamship *Aorangi*, at the wharf in Wellington Harbour. He thinks that at a moderate computation there were over three hundred specimens. He could not capture any, owing to the great height of the light; but they appeared to be chiefly *Mamestra composita* and *Porina signata*. Mr. Hudson points to this as a good instance of the efficiency of the electric light in attracting insects. He has found that an ordinary lamp will not attract more than a dozen or twenty specimens, even under the most favourable circumstances.

In the current number of the *Zoologist* Mr. John Cordeaux has some valuable notes on the occurrence of Pallas's sand grouse in Lincolnshire. Exclusive of the flocks seen near the coast late in August and in September and October, which may probably be referred to birds coming from the interior, and approaching the sea before taking their departure, the number actually recorded as visiting Lincolnshire is, as far as Mr. Cordeaux is able to ascertain, about 184. Making a liberal allowance for flocks seen more than once, he thinks the number may certainly be estimated as considerably exceeding a hundred. Taking the dates as they occur, the number in each flock, and the localities in which the birds have been seen, he is inclined to place the actual number at about 140 to 150 between May 18 and July 28. The number killed was twenty-five, of which sixteen were shot, eight died of poisoned grain, and one was killed on the railway. Mr. Cordeaux has no information which indicates that any sand grouse nested, or attempted to nest, anywhere in Lincolnshire.

The current number (vol. xvi. Part 2) of the Transactions of the Asiatic Society of Japan contains a number of specimens of Aino folk-lore translated literally by Mr. Batchelor, whose name is already known to our readers in connection with Aino studies. Mr. Meik, a civil engineer, employed by the Japanese Government to travel round the Island of Yezo to advise as to the most suitable sites for the construction of harbours, describes his journey. He draws attention to the diurnal inequality of the tides on the Yezo coasts. This amounts to 3 feet at spring-tides along the south-east coast, the maximum rise of a spring-tide being 6 feet, while the range of an ordinary spring-tide is about 4½ feet. The lowest tide at new and full moon occurs about 10 a.m., and the second daily tide reaches a minimum about three days and a half before new and full moon, or at the change of tides. On the south-east coast this minimum afternoon tide occurs about 6 p.m., and only registers a few inches, while on the west coast there is practically only one tide in the twenty-four hours for four days before and one day after new and full moons, and during this period the tide takes sixteen hours to rise and eight to fall. Mr. Parker discourses in his usual very learned way on the Chinese and Annamese languages.

At a recent meeting of the Society of Science of Christiania, Prof. G. Storm demonstrated the identity between Ginnunga Gap, referred to in the *Sagas*, and meaning the "World's End," and the present Davis Straits.

The first discovery of remains of cave-dwellers in Scandinavia has been made in a cave in the Great Carl's Island, in the Baltic, a couple of miles west of the Island of Gothland. Last year a farmer, while digging for mould for a plantation, discovered in a cave or grotto layers of ashes and charcoal mixed with bones. The latter, having been forwarded to the Royal Museum at Stockholm, were found to be the bones of horses, bullocks, pigs, birds, and fishes. In consequence of this discovery, Prof. G. Lindström commissioned Dr. L. Kolmodin to carry out excavations in this cave in a scientific manner; and the result is that indubitable remains of cave-dwellers have been found. The cave is situated about 20 metres above the sea-level, and consists of two parts, an outer one, about 12 metres long and 7 metres wide at the mouth, and an inner one, about 9 metres long and 1½ metre wide; the latter leading into a transverse gallery running south-west and north-east. Dr. Kolmodin began by excavating the layers at the mouth of the cave, and here he encountered, almost in the exact spot where the fire-place had been, a grave 5 metres in length, 2½ metres in width, and 3·2 metres in depth. There are alternate layers of ashes and charcoal, interspersed with remains of the animals named above. The bones of "domestic" animals decrease in quantity downwards, whilst those of seals increase. The explorer found, at a depth of 24 decimetres, fragments of coarse pottery of a primitive kind and some chips of flint; at a depth of 28 decimetres an implement of flint; and in the lowest layer, at 32 decimetres depth, two small drills of bone. Several of the fragments of pottery found below a depth of 24 decimetres bore traces of simple ornamentation. Everywhere in the layers were found bits of granite and chalk, clearly showing that they had been split by fire. Most of the bones had been split or crushed, and the marrow extracted. Among the remains was part of a human cranium. It may be added that the island on which the discovery was made is only a couple of hundred acres in extent, and uninhabited.

The Pekin correspondent of a Shanghai newspaper writes that a special edition of a work on natural philosophy, compiled by Dr. Martin, the head of the Foreign College of Pekin, has been prepared for the use of the Emperor of China, and that sixteen volumes of Macmillan's Science Primers have been translated into Chinese by Dr. Edkins, the well-known scholar, at the instance of Sir Robert Hart, the Inspector-General of Chinese Customs. "These elementary books will supply a want felt in the preparatory science schools which are now being inaugurated, especially in Tientsin. Excellent prefaces to the series, inculcating the advantages of a scientific training, praising the advance made in science in the West, and the valuable contribution or legacy which Sir Robert Hart, amid all his other work for the regeneration of China, is leaving, have been written by the two foremost statesmen in China—the Viceroy, Li Hung Chang, and the Marquis Tseng."

The ninth monthly part of "The Cyclopædia of Education" (Sonnenschein) has been issued. The work will be completed in about twelve parts.

Dr. A. B. Griffiths has in the press "A Treatise on Manures," which will be published by Messrs. Whittaker and Co., of Paternoster Square.

Great pains are taken to secure that the penny science lectures at the Royal Victoria Hall shall be attractive and successful. On November 6, Mr. W. Lant Carpenter delivered a lecture on "Speech-Recording Machines." The following are the announcements for the remainder of the present month: November 13, Mr. Harold Cox, "India"; November 20, Dr. W. D. Halliburton, "The Throat and the Voice"; November 27, Prof. H. G. Seeley, "Underground Heat."

Since September last a system of storm-warnings has been in use on the coasts of the Black Sea; they are issued from the Odessa Meteorological Station in connection with the Central Physical Observatory at St. Petersburg. Signals announcing the approach of strong north-eastern and south-western winds, as well as of storms, are shown at Odessa, Sebastopol, Kertch, Taganrog, Rostoff, Poti, and Batum. The signals are the usual cones and cylinders.

In the Jamaica Weather Report for the month of August, Mr. Maxwell Hall gives an interesting account of the more prominent features of some of the West Indian cyclones observed there during the last ten or twelve years. These hurricanes usually originate in the regions of heavy rains which advance as far north as latitude 15° in August and somewhat farther north in September and October. From November to July the rains withdraw nearer the equator, where the divergence of the air-currents is insufficient for their generation. All the cyclones which have passed Jamaica confirm the theory of the influx of the wind towards the centre. Mr. Hall states that there is a feature often observed in Jamaica which is not noticed elsewhere, viz. after a cyclone has passed, and is moving away, it draws the winds and clouds after it for one or two days, and that this fact enables him to draw conclusions as to the direction in which the cyclone is moving.

THE thirteenth yearly Report of the Forest Meteorological Stations of the German Empire, for the year 1887, published by Dr. A. Müttrich, contains monthly and yearly results for sixteen stations. The temperature and humidity are observed in the open country, in the forests, and in the crowns of the trees. The Report contains, besides, other data of interest, such as evaporation and rainfall, and the dates of first and last frosts.

IN a lecture delivered at Trevandrum by Lieut. Harold Ferguson, and reproduced in the *Madras Mail*, on "Some Popular Errors about Snakes," poisonous snakes are divided into three classes: (1) sea-snakes; (2) viperine snakes; and (3) poisonous colubrine snakes. All members of the first class are poisonous. The second class have flat triangular heads, and may be subdivided into pit vipers and true vipers. The true vipers are recognizable by having scales and not shields on the head, and the pit vipers by a deep depression between the eye and nostril. It is not easy to distinguish the third class at first sight from the harmless snakes, but it is an unfailing sign that the latter are covered on the head with large flat scales, which are absent from the head of poisonous colubrine snakes. With regard to Southern India, the poisonous snakes are not numerous. The largest is the dreaded hamadryad (*Ophiophagus elaps*), which is very rare. Other poisonous snakes found in that region are the cobra, the bungarus or krait, the callophis (four species), two species of *Trimeresurus*, *Daboia elegans*, and *Echis carinata*. In all there are about twelve species of poisonous snakes, five of which inhabit the low country—namely, the cobra, the two species of bungarus, the daboia, and the echis; the others are met with only in the hills.

THE British Vice-Consul at Candia, in Valencia, in a recent report on the agriculture of his district, refers to the insect pests of that province. He says that almost all men and boys there are fond of shooting, and they ruthlessly slaughter the small insectivorous birds. The result is, of course, disastrous to the farmers. The apple-trees in the district have been almost all destroyed by a worm called locally "*bañarriquer*," which eats its way into the trunks of the trees, and then spins a thick cobweb over the branches. The eggs, which number from thirty to fifty in each nest, are easily found; but this is rarely, if ever, done. Strange to say, the worm confines its attention to apple-trees; other fruit-trees flourish there. At Lucerne, in the same district, two species of insect pests are found, both caterpillars—*oruga verde* and *gusaro negro*. The latter is difficult to deal with, as it burrows under the roots of plants, but the former is easily swept off the leaves by a net. The pea crop is attacked by the *cadell*, a worm, and the *blanquita*, an aphis. To complete a list of the ills from which agriculture suffers in that region, mildew has this year attacked the vine.

THE *Journal de la Chambre de Commerce de Constantinople* states that a method of solidifying petroleum has just been discovered. A small quantity of soap is added, and the mixture is heated. When the mixture is allowed to cool, the product can be cut into small cubes like those of compressed charcoal. Thus petroleum can be used as a combustible, it being now easy to transport and manipulate it.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus* ♀) from India, presented by Miss D. Hughes; a Vervet Monkey (*Cercopithecus lalandii* ♂) from West Africa, presented by Miss Helena Blow; a Common Genet (*Genetta vulgaris*) from Andalusia, presented by Lord Lilford, F.Z.S.; a —— Fox (*Canis* ——) from India, presented by Colonel Sir Oliver B. C. St. John, K.C.S.I., F.Z.S.; an Axis Deer (*Cervus axis* ♀) from India, presented by Captain W. Miller; two Hobbies (*Falco subbuteo*) from France, presented by M. P. A. Pichot; a Peregrine Falcon (*Falco peregrinus*), captured at sea, off the coast of Florida, presented by Captain J. Smith; a Knot (*Tringa canutus*), British, presented by Mr. C. Whymper, F.Z.S.; a Pallas's Sand-Grouse (*Syrrhaptes paradoxus*) from Fifeshire, N.B., presented by Mr. John Duncan; an Egyptian Vulture (*Neophron percnopterus*) from North Africa, presented by Captain A. Kent; a Polar Bear (*Ursus maritimus*) from the Arctic Regions, a Ruffed Lemur (*Lemur varius*) from Madagascar, a Yak (*Poëphagus grunniens* ♀) from Tibet, deposited; a Blue Jay (*Cyanocitta cristata*) from North America, purchased; a Crested Pigeon (*Ocyphaps lophotes*), a Bolle's Pigeon (*Columba bollii*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBSERVATION OF FAINT MINIMA OF VARIABLES.—Mr. S. C. Chandler has followed his Catalogue of Variable Stars by another much-needed piece of work. Pointing out how deplorably deficient is our knowledge of the light-changes of such variables as become too faint for ordinary telescopes to follow them, he strongly urges (*Astr. Journal*, No. 183) upon the possessors of the great modern refractors that they could not better employ their high optical powers than in this neglected field. And in order to afford the greatest possible inducement for them to undertake such a research, or at all events to remove as many hindrances out of their way as possible, he has supplied the data necessary for identification for some sixty-nine or seventy stars, the minimum for which is fainter than the 12th magnitude, together with a hypothetical ephemeris for the time of minimum for those stars which are likely to pass through that phase during the next fourteen months. The time of minimum has been assumed to precede that of maximum by 0·45 of the period. Mr. Chandler believes that he has discovered a curious relation between the form of the light-curve and the period. He does not, however, give this relation, but expects that the minima will fall earlier than predicted for stars with periods of from five to ten months or longer than thirteen months, but that in stars with periods from ten to thirteen months the minima will probably fall a little late. Argelander's method of observation is recommended.

OXYGEN LINES IN THE SOLAR SPECTRUM.—M. Janssen has made a very toilsome, not to say somewhat dangerous, expedition in order to determine whether the groups of lines seen in the solar spectrum, and which he had shown to belong to oxygen, were wholly due to the influence of our atmosphere, or partly due to the absorption of oxygen in that of the sun. He therefore resolved to ascend Mont Blanc at a late period in the season, when the cold would be sufficiently intense to secure the absence of any appreciable amount of water vapour from the atmosphere. The station chosen was that of Les Grands Mulets, on account of the cabin there, which would afford shelter to the observers during the period that it might be necessary to continue the observations. The ascent was made on October 13, and the following day was devoted to the adjustment of the instruments. October 15 and 16 were most fortunately very fine days, and the observations were made under the most favourable conditions. The result was to show that both the bands and lines of oxygen, as identified by M. Janssen in the solar spectrum by his previous experiments, are due entirely to the earth's atmosphere. The system of bands—those in the red, in the yellow, and the blue, the intensity of which varied with the square of the density of the absorbing oxygen—was altogether wanting, and the groups of dark lines, viz. A, B, and α, which M. Janssen had found, in the experiments above referred to, to vary as the simple density, were so much enfeebled as to leave little doubt but that they, too, would disappear could we wholly eliminate the influence of our atmosphere. Of course this result does not prove the absence of oxygen from the sun, but merely that it does not show its presence by the same characteristic bands and groups of lines as it does in the case of our own atmosphere.

NEW MINOR PLANETS.—Herr Palisa has discovered three new minor planets, No. 279 on October 25, No. 280 on October 29, and No. 281 on October 31. Of these No. 279 may possibly prove to be Medusa, No. 149; and No. 280 was at first thought to be Oppavia, No. 255, but is more probably a new planet.

COMETS FAYE AND BARNARD.—The following ephemerides for these objects for Berlin midnight are in continuation of those given in NATURE, vol. xxxviii. p. 626:—

1883.	Comet 1888 *d* (Faye). R.A. h. m. s.	Decl. ° ′	Comet 1888 *e* (Barnard). R.A. h. m. s.	Decl. ° ′

DISCOVERY OF A NEW COMET.—Mr. E. E. Barnard, Lick Observatory, Mount Hamilton, discovered a new comet on October 30 (local time). Place at October 31·0399 G.M.T., R.A. 9h. 43m. 22·2s.; Decl. 15° 18′ 52″ S. Daily motion, R.A. + 1m. 32s.; Decl. 9′ *n*. Physical appearance: slightly elongated; 1′ in diameter; 11th magnitude, or fainter; strong central condensation.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 *NOVEMBER* 11–17.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on November 11

Sun rises, 7h. 14m.; souths, 11h. 44m. 13·2s.; sets, 16h. 14m.: right asc. on meridian, 15h. 8·4m.; decl. 17° 38′ S. Sidereal Time at Sunset, 19h. 39m.

Moon (at First Quarter November 10, 16h.) rises, 14h. 7m.; souths 19h. 0m.; sets, 0h. 2m.*: right asc. on meridian, 22h. 25·5m.; decl. 13° 20′ S.

Planet.	Rises. h. m.	Souths. h. m.	Sets. h. m.	Right asc. and declination on meridian. h. m.	° ′

GEOGRAPHICAL NOTES.

THE great Constantine Medal was awarded this year by the Russian Geographical Society to Prof. Romanovsky for his geological work in Russian Turkestan. For more than five years the learned Professor explored various parts of Turkestan, and thus laid the first foundations for the geological knowledge of this region. His first work, "Materials for the Geology of Turkestan," was published in 1876, and it contained the description of eighty-eight species of fossil animals (of which thirty-four were new species) and fourteen species of plants belonging to the Carboniferous, Triassic, Jurassic, and Chalk deposits of Turkestan; the Silurian and Devonian deposits of the region being so greatly metamorphosed as to have most of their fossils destroyed. This first work was soon followed by papers contributed to the *Verhandlungen* of the St. Petersburg Mineralogical Society, in which papers Prof. Romanovsky described the fossils of the Ferghana deposits (Upper Chalk, characterized by their richness in *Ostreæ*, some of which belong to new genera), and the Sarvadan brown-coals, which contain the new lizard *Brontozoum tianschanicum*, and are of the same age as the Connecticut Trias Sandstone. The second part of the "Materials for the Geology of Turkestan," published by Prof. Romanovsky, contains the description of all the palæontological collections gathered in Turkestan by MM. Mushketoff, Syevertsoff, Barbot-de-Marny, and Okladnykh; and no less than 144 species of fossils (of which forty-nine are new) have been described in this second instalment of the "Materials." It was precisely the palæontological work of Prof. Romanovsky which enabled M. Mushketoff to arrive at the remarkable general conclusions as to the great features of the geology of Turkestan, which are embodied in his capital work, "Turkestan," and which rendered it possible for both geologists to draw up the geological map which illustrates it.

AT the same sitting the great medal of Count Lütke was awarded to Th. P. Köppen for his work in botanical and zoological geography. His work on the distribution of Conifers in Russia, published in 1885, is an exhaustive inquiry into the subject, and his numerous monographs on the distribution of insects in Russia, as well as of the squirrel and the stag, as also his monographs about the Siberian cedar, the Scotch fir, the larch, the *Juniperus*, and so on, are most valuable contributions to the botanical and zoological geography of Russia; while his last work on the birth-places of the Indo-Europeans and the Finns and Ugrians (published in the Russian Journal of the Ministry of Public Education for 1886), although made in a new direction, is an important contribution to this much debated subject. Large gold medals were awarded to Prof. M. M. Kovalevsky for his "Modern Customs and Old Law: the Customary Law of the Ossetes"; to Prof. Vs. Th. Miller for his "Ossetian Studies"; and to M. Pirogoff for a statistical work about Kostroma. A small gold medal was awarded to L. P. Zagursky, to whom the ethnography of the Caucasus is indebted for so many valuable works, and all ethnographers will be grateful for his endeavours to save from oblivion and to continue the works of Baron Uslar, which undoubtedly are the most serious researches ever made into the study of Caucasian languages. Gold medals were also awarded to A. S. Vilkitzky for his determinations of the length of pendulum on Novaya Zemlya and at Archangelsk; to N. Y. Dinnik for explorations in Northern Caucasia; and to D. Bulgakovsky for a manuscript work on the inhabitants of the Pinsk marshy tracts. Nineteen silver medals were awarded for various geographical works of less importance.

ON THE ORIGIN AND THE CAUSATION OF VITAL MOVEMENT.[1]

II.

TO this end permit me to go a little into detail concerning nerves. Nerves are processes of nerve-cells composed of fibrils of immeasurable fineness, which, in the so-called axis cylinder of the medullated nerves, are united by a stroma inside a very fine membrane called the axolemma. In proportion to the microscopic dimensions of the ganglion cells, of which the separate nerve-fibres form a part, these latter are for the most part enormously long, many as long as our arms and legs, and that is one of the reasons why the perception of the unicellular nature of the nerves made way but slowly. In fact, it was not easy to accustom oneself amid the microscopic swarm of cells, to find single ones so grown in length that they could be wound about us like a cocoon thread. As it is the task and function of the motor nerves to lead towards the periphery the impulses sent out by their ganglion cells in the spinal cord, their activity always admits of ready perception through the muscular twitching. Even when the nerve is divided and artificially excited at the peripheral end, the muscles betray it. On the other hand, no visible physiological reaction is found at the central origin of the motor fibre when stimulated at the periphery, so that at first we were quite in darkness as to whether in general it conducted centripetally. Nature, however, has presented us with a contrivance by which we are enabled to demonstrate the possibility of such an inverted or centripetal nerve-conduction. The contrivance consists in the branching division of nerve-fibres, so frequently found in muscles, as will at once be seen in a preparation from a frog (Fig. 3). In many muscles these branchings are so arranged that we can use them for an experiment as simple as it is conclusive of nerve-conduction in both directions.

FIG. 3.

FIG. 4.

In the *gracilis* muscle of the frog the nervation is fashioned in the manner displayed schematically upon this diagram (Fig. 4), and in more detail on the following (Fig. 5). In reality the arrangement is like this. Now, if I cut up the muscle according to this diagram (Fig. 6), we get at the tip, *z*, nerve-fibres, which are connected with the muscle-fibres at *o* and *u* only by the branchings at the points *x x*, but which in life served only for the parts of the muscle removed at *f* and *f'*.

An experiment[2] will now convince you that nerves severed from their own muscle-fibres act quite well backwards upon those placed centripetally to them, which they can only do if nerves can also conduct centripetally, and so long as a path is preserved for this through the branchings. If we cut out the neighbourhood of the branchings, it is all over with the reaction of the muscle.

We can make another experiment on the same muscle.[1] We see that when we excite the lower tip of the muscle, only the lower portion twitches and not the upper. The two portions are in fact connected only by means of a very short tendon, the so-called *inscription*, which passes completely through the muscle (*i i* in Fig. 5), so that it really consists of two muscles. If the nerve common to both is stimulated at any point, then both parts of the muscle contract, but if the muscle substance itself is stimulated, then the contraction travels no further from the place where the stimulus was applied than to the limits of continuity of the muscle-fibres.

The power of motor nerves to conduct in both directions is certainly of general significance in regard to the inner mechanism of nerves, but we have only approached it here, because it was necessary for the decisive proof of muscular irritability, as obtained in our last experiment with the *m. gracilis*. Whenever a muscle is provided with a nervation and branchings of the separate nerve-fibres like that of the *gracilis*, some group of muscle-fibres can serve to indicate whether a stimulus has affected this alone or the nerves lying in it as well. If nerves are present at the point of stimulation, and if the agent was at the same time a nerve stimulus, this is shown by the simultaneous contraction of distant parts which are accessible by means of the nerve's power of conducting in both directions. In cases where we can see the coarser nervation, the indirectly produced contractions can be predicted, and these form so certain a criterion of neuro-muscular excitations that by them the presence of the finest nerves may be proved, whose existence might otherwise be quite incapable of proof by any other means, as, for instance, by the use of the microscope. If these contractions are wanting, as was the case in our experiments with the lower end of the muscle, we know that either the spot stimulated is free from nerves, or that the stimulus employed was ineffectual as to the nerves, and affected the muscle substance exclusively. In both cases, then, independent irritability is proved for those muscle-fibres which were directly excited and contracted.

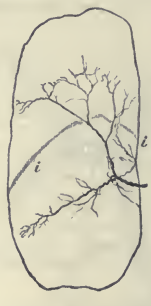

FIG. 5.

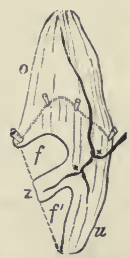

FIG. 6.

Now, since we have just employed an electric stimulus which is equally effectual on muscle and nerve, it follows that we had to do with the first case; that is to say, the muscle showed itself free from nerve at its end. We have reason for specially bringing forward this experimental proof of the absence of any kind of nerves in large tracts of muscle, because it compels those who in spite of all assume the presence of nervous matter in certain microscopic disks and striæ of the muscle-fibre as a whole, to deny that this supposed nervous element possesses any power of conducting in both directions or any irritability at all; for in fact it is not possible to excite the motor nerve of a muscle-fibre by any stimulus whatever applied to the actual terminations of the nerve within the fibre. The facts besides combine to prove, as need hardly be said, yet another proposition—they prove at the same time that pure muscular excitation does not travel back to the nerves.

This may be shown still better with the small pectoral muscles of the frog's skin than with the *m. gracilis*. We need only dissect it in the manner shown in the drawing (Fig. 7), and stimu-

To demonstrate the experiment on the *gracilis*, the muscle was fixed on a white piece of cork by needles, and held by elastic holders, and its image thrown on the wall highly magnified by the so-called Krüss lantern.

[1] Kühne, *ibid.*, pp. 312, 324.

late the spots *n* and M: if we stimulate *n*, everything contracts; if M, the excited half only.

The preparation which you now see (corresponding to Fig. 2), and which shows the nervation of the very thin muscle with all the nerve-endings stained dark with gold, makes that relation clear, for here again in truth the result of morphological research is in gratifying accordance with results obtained experimentally. The muscle is seen to be for the most part free from nerves; indeed the entire nervation with all the nerve-endings might be

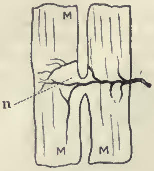

FIG. 7.

said to be formed of one nerve-*line* only, if we disregard the few digressing fibres, which, again, in part are not motor.

Under rather higher powers we see the nerve-endings proper (Fig. 8), the distinct demonstration of which by means of the gold method has now been achieved, in much the same way as here, in all the classes of vertebrates with the exception of the osseous fishes. In all cases these decisive preparations have proved that the vastly preponderant number of the muscle-fibres is entirely free of nerves, and that the nerve-endings are

FIG. 8.

confined to very small spots which we term fields of innervation. Most muscle-fibres have only one field of innervation, very long ones occasionally several, at the most eight. Thus the assumption, opposed to the idea of independent irritability, that muscle-substance is well nigh completely riddled with nerves, is refuted and rejected from the morphological side also.

From the absence of nerves in long tracts of muscle-fibre we immediately conclude that the latter shares with nerves the faculty of independently propagating its own excitation. This is what the beautiful microscopic observations of Sir William Bowman[1] on insects' muscles long since led us to suspect. As in the nerve, so in the muscle, conduction takes place in every direction, and as the field of innervation almost without exception occupies a median position during a normal contraction, the conduction takes place in both directions, towards the tendinous ends. By way of distinction the velocity of conduction is, according to species, temperature, &c., three to ten times less than von Helmholtz fixed it for nerve. As conduction in irritable tissues means nothing else than that one excited spot becomes the stimulus for the adjoining portion at rest, the independent irritability of the muscle-fibre comes into employment in every movement and during the entire duration of life; from the moment that the field of innervation becomes active all the muscle substance remains left to itself, and until the contraction is ended must be regarded as independent and acting in response to its own direct excitation.

Once clear on the fundamental question, and sure as to the method we have to employ in order to stimulate according to choice either muscle- or nerve-substance alone, or both together, we may seek to determine in what respect the irritability of the two components of the motor machine differs. The differences as regards chemical stimulation appear very great; in respect of electric, thermic, and mechanical, on the other hand, only quantitative. However, under chemical stimulation, according to Hering's classical researches,[2] a point formerly overlooked comes into consideration—namely, the complication introduced by the electromotive behaviour of the tissue, an automatic electrical stimulation one might say. When stimulation takes place by moistening the transverse section with conducting liquids, it is indeed difficult, if not impossible, to trace the chemical factor in presence of the electrical. Gaseous stimuli alone, like ammonia, have thus far remained free from the suspicion of acting electrically. To these a few others of similar action, such as bisulphide of carbon,[3] have been added, and such as are conveyed to the muscle by blood-vessels, and bathe the fibres from all sides. With these in particular we may class distilled water, which is excessively destructive to irritable substances, von Wittich[4] being the first who showed how strongly it stimulates muscles, while killing nerves without excitation. But, again, with this kind of stimuli, we cannot at present tell whether they do not set up in the tissues, over narrow but numerous areas, excitatory electric currents, thus working only indirectly by way of auto-electric stimulation. And since, finally, the same might apply to the thermic and mechanical actions which likewise arouse demarcation currents in the muscle—that is, to all stimuli—we find ourselves in the presence of the possibility of reducing all irritability to a reaction to electrical processes, and of seeing vital electricity elevated into immeasurable importance.

The means by which muscle may be stimulated interests us, in the first place, on this account—to ascertain, once for all, how it procures its excitation *in life*, or what may be the action of nerve upon it. Did we know that, we should have grasped at the same time the nature of nervous activity.

Nerves end blindly in the muscles; as a rule they are not even finely pointed, and still less do they spread out diffusely in such a way as might make the true ending difficult to find. They end quite distinctly. But the ends always lie beneath the sarcolemma, in such a way that no foreign tissue intrudes between them and the muscle, so that what is fluid in the muscle can directly moisten the nerve. The sublemmar nerve is clothed with nothing else than the axilemma. The nerve never penetrates into the depths of the muscle-substance; on the contrary, it remains confined to the sublemmar surface of the contractile cylinder or prism. Each nerve-end consists of several branches, like antlers, arising by division, which together

[4] "Experimenta quaedam ad Halleri doctrinam de musculorum irritabilitate probandam instituta," Königsberg, 1857; and *Virchow Archiv*, vol. xiii. 1858, p. 421. In these papers, with the discovery of the excitation of muscle by distilled water, appears without doubt the first fact which overthrew the old theory of the equal irritability of muscle and nerve.

form the terminal nerve-branch. Apart from the form of the antlers, this short description is exhaustive for many animals, since neither in the sublemmar nerve need any special additional structures occur, such as nuclei, nor any kind of modification of the muscle-substance in the field of innervation. There is much to indicate that the nerve-fibre proper, or axis-cylinder, does not change its constitution in passing through the sarcolemma, still it is to be remarked that the twigs of the terminal branches, although as long as they live often apparently longitudinally striated, have not yet, even in the most favourable stainings, been found to present the general fibrillar structure of nerves.

According to these results of morphological research, it appears that contact of the muscle-substance with the non-medullated nerve suffices to allow the transfer of the excitation from the latter to the former. The only strange thing is that in reversed order excitation of the muscle never extends to its own nerve. This is still stranger because, according to Matteucci's well-known discovery, a *foreign* medullated nerve simply laid upon the muscle is powerfully excited by the contraction—so powerfully that the smallest contracting muscle barely touching it in more than a mere point excites the strongest nerve, while, on the other hand, we never see muscles excited by nerves which are merely pressed against them.

In the investments, then, of the nerve and the muscle-substance appears to exist one of the elements which admits the neuro-muscular excitation *exclusively* to the field of innervation, and among those investments it need not be the medullary sheath. The delicate membranes of the sarcolemma and neurilemma suffice, for muscle cannot be excited by superimposed *non*-medullated nerves. At any rate, I have tried in vain to excite muscles by the most intimate contact of the fine terminal ramification of the optic nerve in the retina or the *n. olfactorius* from the pike, or even the delicate nerves of Anodonta, by stimulating these non-medullated nerves.

If we imagine the activity of the nerve to start with a chemical process, and that a chemical stimulant, as du Bois-Reymond[1] once suggested, is, at the same time, secreted in contact with the muscle, we understand very well the necessity of direct contact, and in this case it would suffice if the sublemmar nerve were to run in *any* form for a short distance under the sarcolemma. The branching then would mean the enlarging of the contact. But however rich and intricate the ramifications may be, we can by no means say they display throughout the principle of increase of superficies; on the contrary, they are often astonishingly poor and small. As concerns their form, they are *not* irregular, but so strikingly uniform that this point deserves particular attention as being apparently indispensable for innervation.

Instead of describing the forms, allow me to show you the object itself in a selection taken from the most diverse vertebrates. First from the Amphibia (Fig. 9): rod-like branchings with long outstretched twigs, a form which crops up again in a remarkable way in many birds. The rule here is asymmetry of the divisions: all the twigs have the form of a bayonet.

The following preparation shows the termination in the dog (Fig. 10). Here the branches are crooked, and hence quite divergent, so that the points of agreement with the form of the Amphibia are at first overlooked. But if we examine the divisions, you will remark that these are again unsymmetrical and give off branches whose ends lie very diversely removed from the common place of origin. The ends are, as a rule, turned towards each other, and often so approximated that it is at times troublesome to find the gaps between them, and if they do not lie in the same plane they appear to be united into a ring. In other cases one end overlaps the other, but we then find that all the points of the branches which are turned towards each other lie at unequal distances from the nearest bifurcation. This law holds good in all the thousand cases of motor endings thus far observed, and shows a strict order in the apparent chaos of these structures. And yet among the organic forms there is scarcely one which varies so much in other respects, and often is so inextricably complicated as this.

The drawings (Fig. 11, from the muscles of the guinea-pig, and Fig. 12, of the rat) and a preparation from a lizard (Fig. 13) may serve as a voucher for the truth of the above statement. We see there everywhere the hooks making their appearance with a short and a long claw, like the swivel we hang our watch on in the pocket.

[1] "Gesammelte Abhandlungen zur allgemeinen Muskel und Nervenphysiologie," vol. ii., p. 700.

The voluntary muscles of all vertebrates and of many invertebrates consist of fibres, the contents of which are pefectly regularly disposed in layers and transversely striped. For shortness, this striped mass may be called "rhabdia." This it is which has been universally identified with the contractile substance. But it has been ascertained that in many cases the nerve-ending does not come at all into direct contact with the rhabdia, but with another mass, which is highly nucleated and of pap-like softness. This latter is unstriped, and has all the appearance of protoplasm. It occurs in very varying quantity under the nerve-antler; in Amphibia, where the sublemmar nerves run out in a long course, it is not apparent as a separate layer, but it occurs more abundantly in the same measure that the branchings retract, and the field of innervation becomes smaller. At first it is found chiefly between the twigs, in the intervals of the branching, and then in the form of a sole, which, among the much-contorted branchings of reptiles and mammals,

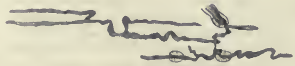

FIG. 9.

FIG. 10.

grows thicker, till it sometimes in some nerve-eminences forms quite a thick cushion. Since we have succeeded in making the nerve-endings visible in uninterrupted series of very fine sections of mammalian muscle stained with gold, there can no longer be any doubt that the complete separation of the sublemmar nerves from the rhabdia by measurable layers of sole-protoplasm, though not the rule, is yet by no means rare, and that many muscles possess no other sort of nerve-endings than such as these with apparently indirect contact.[1]

It would be difficult to understand why the innervation should have in some muscles, as in the Amphibia, no intermediate layer, while having in the majority of cases an interrupted layer, and in others a continuous layer of varying thickness to traverse. But when we consider what the substance of the sole is, of what it consists, how it is distributed, and when we know its origin, it appears that it is identical and stands in continuous connection with the long-known second constituent of muscle-

FIG. 11.

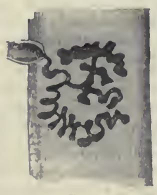

FIG. 12.

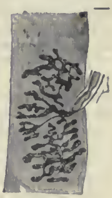

FIG. 13.

fibres, of which, as well as of the rhabdia, the fibres are composed. It is that substance, considered by Max Schultze to be the protoplasmic remnant of the cells composing muscle, which occurs in greatest amount around the nuclei of muscle, and extends in long threads throughout the entire muscle-fibre. So many transverse connections occur on the very numerous stronger and finer nucleated threads that the whole mass, called sarcoglia, becomes a trellis-work almost of the same fineness as the better-known transverse striation of the rhabdia, and everywhere surrounds and interpenetrates the latter. This minute internal structure of muscle has only become at all well known since the introduction of gold staining, thanks especially to Messrs. Retzius and Rollett.[2] Had it been suspected earlier, and had we appre-

[1] Kühne, *Verhandlungen des Naturhist.-medicinischen Vereins zu Heidelberg*, Neue Folge, vol. iv. pp. 4, 5.

[2] G. Retzius, "Biologische Untersuchungen," 1881. A. Rollett, "Untersuchungen über das Bau der quergestreiften Muskelfaser," *Wien. Akad. Denkschr.*, vol. xlix., 1885.

ciated the volume of the sarcoglia, whose existence is thereby shown, and which rivals that of the rhabdia, we might have studied this component of muscle in its physiological relations to contractility, as well as in its morphological and genetic relations, which are the only ones yet known.

If now, in many cases, it appears that the nerve comes in contact only with the surface of a thick layer of sarcoglia, while the rhabdia everywhere is covered by very fine layers of the latter, whose absolute absence in the field of innervation can nowhere be demonstrated, we have to conclude that in general the nerve does not act directly upon the rhabdia, but only on the sarcoglia. This at once gives the latter a physiological interest. We have to ask whether the glia is the medium that conducts the stimulus between nerve and rhabdia, or whether it is itself the contractile element, while the rhabdia has a signification other than that formerly attributed to it when we were completely ignorant of the glia.

All contractile substance requires the co-operation of an elastic element. Where is this to be found in the muscle-fibre? The envelope of the sarcolemma, which is certainly elastic, but delicate, and whose mass is almost infinitesimal compared with that of the muscle-fibre, cannot satisfy the requirement; but more solid structures freely distributed in the paste-like sarcoglia could perhaps do so, and such we find in the rhabdia, in the form of prismatic particles, ranged with such constancy and with such regularity longitudinally and transversely, that we may hold them to be the elastic element. Then the sarcoglia would become the contractile element, and the nerve would have an easier task.

I could wish that this view might be accepted as an hypothesis. As far as I can see, it does not contradict experience, for it only puts back the muscle nearer to the protoplasm and to all that is contractile, and so far coincides with experience that we find muscles in the same measure less elastic and more sluggish in protoplasmic movement the richer they are in sarcoglia, as in the case of the red muscles, nucleated and rich in glia, which contract more slowly but with greater power than the white muscles, poorer in glia, which are quick and spring-like, and also the sluggish embryo muscles, in which glia predominates because as yet but little protoplasm has been converted into rhabdia; and further the cells of unstriped muscle-fibre, which are wanting in the regular transverse striation, and contain, as it appears, besides more abundant glia, an elastic material of special form and arrangement.

The hypothesis would be overthrown if contractile fibrils were found in which no sarcoglia was to be detected. But even in the finest fibrils of *Stentor*, the structure of which Bütschli [1] has recently elucidated, we must hold the significance of punctated transversely penetrating indentations to be protoplasmic, and we can therefore scarcely expect ever to find a contractile thread in which nothing whatever should be found of the primitive contractile material such as it everywhere exists.

Of late, this view [2] has been defended from the purely morphological side,[3] on the strength, namely, of the very fine reticular structure of protoplasm to which more attention is being paid, and which is demonstrable on objects of all grades of organization. Protoplasm, in fact, is not so formless as at first appeared, but shows a structure comparable with nothing better than with the appearance presented by a transverse section of muscle with its glia framework stained with gold. We may expect that these reticular structures, whose consistency appears to vary extraordinarily, will some day lead to the establishment of a fruitful hypothesis of the inner mechanism of protoplasmic movement, in place of that held hitherto, which affords no glimpse into the essence of vital mechanical work.

Compared with this larger problem, that of the causation of vital movement appears the more accessible of the two, the latter being considered as a physiological inquiry after the constitution of the normal stimulus by which work is done. Perhaps, indeed, the answer is to be looked for from the most perfected organization of muscle, where the iniatory process is localized by a distinct nerve-ending, rather than from the primitive organization, where the excitation may set in at any place, and lies in the protoplasm itself. We know distinctly that the muscle-wave begins in the field of innervation, for we

[1] "Dr. H. G. Bronn's Classen und Ordnungen des Thierreiches," neu bearbeitet von O. Bütschli, Leipzig und Heidelberg, 1888, vol. i. p. 1298.

[2] Kühne, "Neue Untersuchungen über motorische Nervenendigung," *Zeitschr. Biol.*, vol. xxiii. pp. 88-95.

[3] A. van Gehuchten, "Étude sur la structure intime de la cellule musculaire striée," *La Cellule*, vol. ii. p. 289.

have long seen the natural contraction in the interior of transparent insect larvæ starting from the nerve-eminences. We know this also from the experiments of Aeby, who followed the muscle-wave myographically from the nerve-line onward, and now we are able to display the beginnings of the contraction as local thickenings at the point of attachment of the nerves caught and fixed by sudden hardening. Since the nerve grasps the muscle in a restricted region, it expends its action upon this exclusively; that which follows on as muscular activity is the nerve's work no longer.

Galvani and his successors for more than a century suspected that nervous forces were electrical, and, in reality, the celebrated champion of electro-physiology in our day has been able with the galvanometer to render the excitation of nerves, unattached to muscles or ganglion-cells, evident as the negative variation of the natural nerve-current, to cause movement of a magnetic needle instead of a muscle, or to put the needle in the place of sensation. After this no consideration of the nature of nervous activity is conceivable which does not take into consideration this discovery of du Bois-Reymond's—least of all where the nerve has to excite something with which it is not fused, like muscle, but which it only touches, and that not directly, while still invested by the axolemma. Only during excitation, as Ludimar Hermann has taught us, are electric currents issuing from the nerve through its conducting surroundings, in which the course of these currents of action is to be estimated from the duration of the negativity of the nerve-tract excited, and from the speed of propagation of the nerve-wave, if we know the conductor and the disposition of the nerve. The motor ending fixes the latter, and so peculiarly that we can only presuppose from it a furthering of the excitor effects of the currents of action.

The currents of action of muscle, whose electromotive behaviour agrees so wonderfully with that of nerve, have long been proved to produce excitor effects, although only powerful enough to act upon nerves; but there are also, under certain conditions discovered by Hering, such effects from nerve to nerve.[1] Is the possibility, we may hence ask, to be excluded, of one muscle exciting another, and is it quite impossible that a nerve only throws a muscle into contraction by means of its currents of action?

The first question we can answer. I will do so by a simple experiment. Two muscles, the nerves of which are disposed of by poisoning with curare, need only to be pressed together transversely over a narrow area to make a single muscle of them of double length, in which the stimulation and contraction are propagated from one end to the other. Since the transference from one muscle to the other is done away with as soon as we bring the finest gutta-percha between the muscles as an insulator, or gold-leaf as a secondary circuit, the first muscle must have excited the second electrically.[2]

THE ASTRONOMICAL OBSERVATORY OF PEKIN.

IN the course of a lecture delivered before the Pekin Literary Society, on the Astronomical Observatory of the Chinese capital, Prof. Russell said that it is the oldest in the world. The oldest in Europe is that of Denmark, founded in 1576 by Frederick III., at which Tycho Brahé made his famous observations. The Royal Observatory at Paris was not opened till 1671, and that of Greenwich three years later. The Pekin Observatory was established in 1279, in the reign of Kublai Khan, the first emperor of the Mongol dynasty, and three of the original instruments yet remain. In 1378, these instruments were probably used in observing Halley's comet, and they will be used twenty-two years hence to witness its next return. If the visitor enters by a door in the south wall of the Observatory, he comes into a court running east and west. In this court are kept the three original instruments. There were four at one time, but the fourth, a celestial globe, has disappeared. Kuo Shouching, a Chinese astronomer, who flourished in the reign of Kublai Khan, was the maker of these. Before their construction, bronze astronomical instruments, which were made about the year 1050, were used, first at K'ai Fêng Fu, the capital of Honan, whence they were removed to Pekin. Kuo Shouching found these

worn out by age, and otherwise unsuitable, as the height of the Pole differed by 4°; and so he constructed four instruments, of which three now remain. In the east end of the court is the equatorial armillary, which is made of bronze, and consists of (1) a massive horizontal circle, held up at four corners by four dragons, each of which with one upraised palm supports the bronze circle, while round the other palm a chain is passed and fastened behind to a small bronze pillar,—the dragons are themselves works of art; (2) a double vertical circle firmly connected with the horizontal circle at its north and south points, and supported at its lowest point by a bronze pillar. On the vertical circle, which, like the other, is fixed, at a distance equal to the latitude of Pekin, that is 40°, are two pivots corresponding to the North and South Poles. Revolving round these pivots are two circles, one double, corresponding to the solstitial colure—that is, the great circle passing through the Poles and the solstices; the other single, corresponding to the equinoctial solure—that is, the great circle through the Poles and the equinoxes. Half-way between the Poles is another circle, which corresponds to the equator, the rim of which is let into the two colure circles. There is also another circle, making with the latter an angle of $23\frac{1}{2}°$, and corresponding to the ecliptic. Finally, inside these circles, all of which revolve together round the polar axis, there is another double circle, representing the polar circle or declination, and between the rims of this double circle revolves the hollow tube through which observations were made. It is probable that there were originally threads across the tube to define the line of sight. There are in the circles $365\frac{1}{4}°$—that is, a degree for each day in the year—and each degree is subdivided into divisions of 10′ each. When using this instrument the observer turned round the inner circle till the heavenly body was sighted in the centre of the tube, and then the distance of the star was read from the Pole on the polar circle, and its position on the equator by the equatorial circle. The complex construction was in some particulars of no use whatever: the ecliptic and one of the colures were useless. At the west end of the court are the other two instruments, the equatorial, or astrolabe, and the altitude and azimuth instrument. The former is remarkably simple in its construction. There is a fixed bronze circle placed parallel to the equator, and there is another double circle perpendicular to it, which moves round an axis passing through the centre of and perpendicular to the equatorial circle. Of course there is also the hollow tube for observation. This instrument is free from the clumsiness and complexity of the first-named instrument, and in the form of its mounting much more closely resembles those in use at present in all Observatories than the other instruments. The altitude and azimuth instrument consists of two circles, one horizontal and fixed, the other vertical and movable round an axis passing through the centre of the horizontal circle, and was used to observe the altitudes of the heavenly bodies and their distances from the north and south points. It is curious to observe that all these instruments are exactly similar to those constructed by Tycho Brahé, the great Danish astronomer, who was the first European to make astronomical instruments of metal. And thus we see that the Chinese anticipated European astronomers by at least three centuries, and that the former had at that very early date attained great proficiency both in the science of astronomy and the art of metal-carving. Verbiest, the Jesuit father, says that these instruments had, at the beginning of the present dynasty, fallen into disrepair. The truth was that they were far too clumsy, and were so heavy that it took several men to move them; and in some positions, from the profuseness of ornament, the stars could not be observed at all. Besides they had got out of position, and there were no appliances for righting them. It is more than probable that during the latter part of the Ming dynasty astronomy had been neglected, and so the old instruments fell into disuse. In the year 1670, so bad were the old instruments, that Verbiest was ordered to make six new instruments. It appears that when the high Ministers of State were ordered to go to the Observatory, and make certain observations, the calculations of Verbiest were verified as correct, while those of Wu Ming Hsuen, the Chinese astronomer, were proved to be wrong. And so Verbiest was intrusted with the calculation of the calendar and the construction of these instruments, which were of the same general character as the old instruments, but much more accurate, and more easily adjustable. The circles are divided into 360°, and each degree into six parts of 10′ each. By means of the diagonal scale and a movable divided scale, the observer could, on the new instruments of Verbiest, read to 15″, instead of 10′ as in the old instruments. Since the time of Verbiest two more instruments have been added—namely, an altitude and azimuth instrument, in the fifty-fourth year of Kang Hsi (1715), the other an equatorial armillary in the ninth year of Khien-Lung (1745). The former is said to have been a present from Louis XIV. to the emperor, but by some it is attributed to a German Jesuit, named in Chinese Kilian, and is remarkable for the total absence of ornamentation, and for the degrees being marked in foreign numerals. One of the most curious objects in the Observatory is the Qw'ei Ying T'ang, a three-roomed building lying a few yards to the south of the steps. It is evidently very old. In it is a stone slab 16 feet 2 inches long and 2 feet 7 inches broad, with a groove on both sides, and raised about 3 feet above the ground. At the south end of the slab is a brass pillar, which was formerly 8 feet high, but to which the present dynasty have added 2 feet more, extending to the roof, and at its summit is a small circular hole $\frac{3}{10}$ inch in diameter. Another brass pillar 3 feet 5 inches high stands at the north end of the slab. At noon the sun shines through the little hole in the roof, and throws an elliptical shadow of the sun on the slab, or on the brass pillar at the north end about the winter solstice. By observing the distance of the sun's image from the foot of the south brass pillar the solstices and equinoxes were determined. For instance, at the summer solstice the distance should be 2 feet 9 inches. The instruments of Verbiest are almost perfect of their kind, and will remain a lasting memorial of the industry and genius of the devoted missionary. At the time that he made them they were growing out of date in Europe. The telescope had already begun to be used largely in astronomical observations, and Verbiest must have known of it. The question arises, How does it happen that the Chinese, who in the thirteenth century were far ahead of Europe in the construction of these instruments, seem to have made no headway since? Many reasons can be given, but the chief one is that with them the main object of making astronomical observations was to regulate the calendar, and to give the time to the people; and for this accurate instruments were not needed, and their want was never felt. The greater problems of the heavens never seriously attracted the attention of the Chinese astronomers. The Astronomical Board consists of eighteen officials, with the fifth prince, an uncle of the emperor, at their head. There are, including students, altogether 196 persons attached to the Board. The privilege of becoming a member of this Board has become hereditary, though it is not of necessity so. The policy, however, pursued by the Board, of keeping secret the book tables of the sun and moon, and everything used in regulating the almanac, tends to encourage the hereditary principle. No one can see them but the relatives of the Board; and so vacancy after vacancy is filled up by members of the same family as the predecessor, and as the office is an honorary, and not a lucrative, one, the people do not grumble at their exclusion. The principal duty of this Board is to prepare the calendar, the most important book published in China. Besides astronomical facts, it gives the lucky and unlucky days, on the latter of which no Chinese will transact the least business. Another duty is to observe eclipses, and this appears to be the only occasion on which the instruments are still used. On every New Year's Eve, at midnight, astronomers from the Board seat themselves in the Observatory, and watch the way in which the wind blows a number of banners which are hung around. As the wind blows, so will the new year be. This year the wind blew from the north-east, the fortunate direction, and therefore it will be a year of long life and plenty.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following were elected Fellows of St. John's College at the annual election on November 5: W. N. Roseveare, B.A. (mathematics), Master at Westminster; E. H. Acton, B.A. (botany and chemistry); F. W. Hill, B.A. (mathematics); T. Darlington, B.A. (philology), University Scholar, London, Head Master of Queen's College, Taunton, author of "The Folk-Speech of South Cheshire"; H. F. Baker, B.A. (mathematics), bracketed Senior Wrangler in 1887.

SOCIETIES AND ACADEMIES.

LONDON.

Mineralogical Society, October 30.—Anniversary Meeting. —Mr. L. Fletcher, President, in the chair.—The Hon. Secretary, Mr. Scott, read the Annual Report, which showed that the

state of finances was not unsatisfactory. The excess of assets over liabilities was £247 6*s.* 11*d.*, and the expenditure on the Journal during the year had been £79 13*s.* 9*d.*, being about the average of late years. The elections to the Society during the year had been six, of whom one was an Associate. The Council had to regret the loss by death of one of their Corresponding Members, Prof. vom Rath, of Bonn, of whom an obituary notice by Prof. Lewis appeared in No. 37 of the Journal. Mr. Solomon Birkett, one of the Associates, had also died, having been killed by a railway train near Whitehaven. Three meetings had been held since the last anniversary, two in London, and one in Edinburgh.—The following is the list of officers and Council elected for the coming session:—President: R. H. Scott, F.R.S. Vice-Presidents: Rev. S. Haughton, F.R.S., and Dr. Hugo Müller, F.R.S. Council: Prof. J. W. Judd, F.R.S., Prof. E. Kinch, Prof. W. Ivison Macadam, J. J. H. Teall, Prof. A. H. Church, T. M. Hall, J. Stuart Thomson, Major-General C. A. MacMahon, Dr. C. A. Burghardt, H. A. Miers, R. H. Solly, and Dr. J. M. Thomson. Treasurer: Prof. T. G. Bonney, F.R.S. General Secretary: L. Fletcher. Foreign Secretary: T. Davies. Auditors: B. Kitto and F. W. Rudler.—The President then delivered an address which will be printed in the next number of the Journal.—The following papers were read:—On large porphyritic crystals of feldspar in certain basalts of the Isle of Mull, by T. H. Holland, communicated by Prof. Judd, F.R.S.—Note on the crystalline forms of silicon and carbon, by Prof. Judd, F.R.S.—On the supposed fall of a meteorite stone at Chartres, Eure-et-Loire, in September 1810, by the President.—On percylite from a new locality, by the President.—On various twins of calcite, by H. A. Miers.—A description of a new polarizing microscope, by Allan Dick, communicated by J. J. H. Teall.—Note on Colorado hydrophane, by Prof. A. H. Church, F.R.S.

Paris.

Academy of Sciences, October 29.—M. Janssen in the chair.—On the telluric spectrum at elevated stations, and particularly on the spectrum of oxygen, by M. Janssen. We print elsewhere (see "Our Astronomical Column") a brief account of M. Janssen's conclusions.—Decomposition of the phases of a continuous movement by means of successive photographic images taken on a tape or band of sensitized paper while being unrolled, by M. Marey. In order to complete the researches lately communicated to the Academy, the author here submits a strip of sensitized paper on which a series of images has been fixed at the rate of twenty per second. The process, as now perfected, will allow of successive images being taken of a man or an animal in motion, without the necessity of operating before a dark ground.—On the alleged subsidence of the ground in the centre of France, between Lille and Marseilles, by General Alexis de Tillo. The author traverses the conclusions arrived at by M. Goulier in his communication on this subject inserted in the *Comptes rendus* of August 20, 1888.—Survey of the Upper Javary, by Admiral de Teffé. A short account is given of the expedition undertaken in 1874 by Baron de Teffé and Don Guillermo Black, to determine the frontier between Brazil and Peru, where those States are conterminous in the valley of the Javary, a headstream of the Amazons.—On vapour-tensions, by M. Ch. Antoine. Some new relations between tensions and temperatures are worked out theoretically.—Photography applied to the study of electric discharges, by M. E. L. Trouvelot. During a series of experiments carried out for the purpose of studying the electric spark, the author has been led to repeat the interesting researches made in 1884 by M. E. Ducretet, and published in the *Comptes rendus* for December 1 of that year.—On the separation of cobalt and nickel, by M. Baubigny. Here the separation is effected by the method of the nitrites—On the chlorureted derivatives of acetylacetic ether, by M. Genvresse. The monochlorureted derivative of this ether was prepared by M. Allihn, and the bichlorureted by M. Conrad. But doubts having been thrown on the formulas determined by them, the author here resumes the study of these compounds.—On the employment of the bichloride of mercury as a therapeutic remedy and a prophylactic against Asiatic cholera, by M. A. Yvert. During his recent residence in Tonquin, the author successfully employed this preparation for the cure of cholera in doses varying from 0·02 to 0·04 gr. in twenty-four hours. Of forty-five patients so treated nine only succumbed, or about 20 per 100, the normal rate in that region as in Europe being 66 per 100. It was also administered to convalescents in districts where the epidemic had again broken out and had already made one victim. None of those who took this preventive medicine was attacked.—M. Raphael Dubois contributes an account of some new researches on the action of the chloride of ethylene on the cornea; and M. C. J. A. Leroy describes the normal form of the cornea of the human eye.

FOSSILS OF THE BRITISH ISLANDS.

Fossils of the British Islands, stratigraphically and zoologically arranged. Vol. I. Palæozoic. By Robert Etheridge, F.R.SS.L. and E. (Oxford: Clarendon Press, 1888.)

GEOLOGISTS and palæontologists will hail with satisfaction the publication of the first volume of Mr. Etheridge's "Fossils of the British Islands," which has just issued from the Clarendon Press. Most of us who have been occupied in this department of science have long been expecting the appearance of this work, for those who have laboured much among fossils know full well the value of such a help to study.

When the late Prof. John Morris, in 1854, brought out the second edition of his "Catalogue of British Fossils," only about 4000 species were known, and yet so great was the need of some such aid, that the publication of that catalogue has been referred to as marking an epoch in British palæontological studies. During the thirty-four years which have since elapsed, palæontology has made most rapid strides, and Mr. Etheridge now estimates the number of British fossils at nearly 18,000 species. So vast an increase is of itself sufficient to show the necessity for some enlarged work of reference, which should bring the accumulated material within the grasp of the working palæontologist; and such is the scope of this catalogue of the "Fossils of the British Islands." Indeed, Mr. Etheridge tells us, in his preface, that it was to facilitate his work as Palæontologist to the Geological Survey of Great Britain that he, in the year 1865, commenced the manuscript of this tabular arrangement of fossils.

Those of us who have had the advantage of working for a number of years beside the author, and have been able to use these manuscripts, which were ever placed freely at our disposal, have learned to know their value, and to look forward with no little desire to the time of their publication.

The works of reference for fossil species, which have hitherto been available, are D'Orbigny's "Prodrome de Paléontologie" (1850), Bronn's "Index Palæontologicus" (1848), and Morris's "Catalogue of British Fossils" (1854). The first of these is divided into stratigraphical sections, with an index of species at the end. Bronn's "Index" is arranged alphabetically throughout, and the horizon of each species is indicated by letters referring to a table. The alphabetical arrangement is convenient for obtaining references to authors and descriptions, but the second reference for the horizon is troublesome. Morris's "Catalogue" is divided into zoological sections, similar to those adopted by Mr. Etheridge, and in each section the genera and species are placed alphabetically, with references to authors and descriptions, the chief horizon of each species being given on the right of each page.

In neither of these catalogues have either references or horizons been given in such detail as in the work now before us, which is not only a catalogue of all known British species, but also a table giving their full distribution in time, with voluminous references to the most important descriptions and figures; and the synonymy has been, as far as possible, brought up to date. The tabular form adopted by Mr. Etheridge has necessitated the division of the book into several stratigraphical groups; and consequently this first volume, which includes all the species recorded from Palæozoic formations, is divided into four sections: (1) Cambrian and Silurian; (2) Devonian or Old Red Sandstone; (3) Carboniferous; (4) Permian or Dyas.

In an appendix, three of these sections are repeated, so as to bring the work down to the year 1886.

At the head of each section the divisions of the formations which have been adopted are explained, and the important localities are noted at which the beds occur. Each page is arranged with vertical columns, one for every stratigraphical division, and on the left are the names of the genera and species, stars being placed opposite the latter, in the appropriate column, to mark their distribution. One column indicates those forms which pass up into the next higher section, while on the right the references are given.

The strata included in Section 1 are thus divided:—Cambrian, including (1) Harlech and St. David's beds, with Longmynd, Llanberris, and Bray Head; (2) Menævian; (3) Lingula Flags; (4) Tremadoc. Lower Silurian, including (1) Arenig; (2) Llandeilo; (3) Caradoc or Bala; (4) Lower Llandovery. Upper Silurian, including (1) Upper Llandovery; (2) Woolhope Limestone; (3) Wenlock Shale: (4) Wenlock Limestone; (5) Lower Ludlow; (6) Aymestry; (7) Upper Ludlow; (8) Tilestones or Passage Beds and Downton Sandstones.

The second section, Devonian or Old Red Sandstone, is divided into lower, middle, and upper beds, and the third or Carboniferous section is divided into (1) Calciferous Series; (2) Lower Limestone Shales; (3) Carboniferous Limestone; (4) Upper Limestone Shales (Yoredale); (5) Millstone Grit; (6) Lower Coal Measures; (7) Middle Coal Measures; (8) Upper Coal Measures.

The fourth section, Permian, is divided into (1) Passage Beds; (2) Rothliegende; (3) Marl Slate; (4) Lower Limestone; (5) Middle Limestone; (6) Upper Limestone.

Under each of the four sections the plants are first dealt with, the genera being in one alphabetical series; and then follow the animals, which are divided into the following groups, the genera in each being arranged alphabetically—namely, Rhizopoda (divided into Spongida and Foraminifera), Hydrozoa, Actinozoa, Echinodermata, Annelida, Crustacea, Arachnida, Myriapoda, Insecta, Polyzoa, Brachiopoda, Conchifera, Gasteropoda, Pteropoda, Cephalopoda, Pisces, Amphibia. In the appendix the Placophora and Heteropoda are separated from the Gasteropoda.

There can be no question but that in works of reference the alphabetical order is the simplest, and therefore the best, where it can be adopted; but in the present instance it was obviously necessary to make geological divisions; and the zoological groups which Mr. Etheridge has used are nearly the same as those of Prof. Morris's "Catalogue," which in practice has been found very easy for reference. This arrangement has the advantage also of bringing together the members of each of the groups, and the index of species supplies what further help is needed.

The zoological divisions being merely for convenience, little need be said about them; but, at the same time,

there are one or two points which may be noticed in passing. The Sponges are retained as a sub-group of the Rhizopoda in the sub-kingdom Protozoa. Possibly the first pages of this work were in type before the separation of the Spongida from the Protozoa, which is now generally accepted, was so strongly insisted on by biologists. It is well, however, for students to be reminded that the Sponges are regarded by most naturalists as presenting a higher type of organization than is found in the Protozoa.

In the first part of this volume the name Conchifera is used for the bivalve Mollusca. This is to be regretted, inasmuch as the term is incorrect, unless it can be used to include all the shell-bearing Mollusks. In the latter part of the appendix, Pelecypoda is used instead of Conchifera. It may be that the latter name has priority, but surely it is not so appropriate nor so correct as that of Lamellibranchiata, which has for so long been in general use; and it seems questionable whether this reversion to old names, for groups of animals, is justifiable.

Perhaps the most difficult part of the work which Mr. Etheridge has undertaken is the correction of specific synonymy, and specialists in certain groups may possibly be inclined to differ from him; but those who have done most in the endeavour to rectify the synonyms of fossil species will best appreciate the difficulty of the task, and be most ready to make allowance for any difference of opinion in these matters.

There are few palæontologists who have such a grasp of the entire range of British fossils as Mr. Etheridge, and probably none better qualified for the work, the first part of which is here so successfully accomplished. The author is to be congratulated on the completion of so much of his task, and on the admirable manner in which it has been printed and published.

That the book has been printed by the Clarendon Press is sufficient guarantee of its excellence. The careful typing and arrangement, as well as the clear printing and good paper, are all that could be wished for, and add greatly to its value.

It is much to be desired that the Secondary and Tertiary portions of this catalogue should speedily be in the hands of geologists; but one reads with regret, in a note at the end of the preface, that the pressure of official duties will prevent the author preparing these parts for publication, although the manuscript is practically complete. It is sincerely to be hoped that the delay may be of short duration, and that Mr. Etheridge will shortly see his way to the completion of this valuable work, which every geologist and palæontologist ought to possess, as it must of necessity be for many years the standard work of reference for British fossils.

E. T. N.

YORKSHIRE LEGENDS AND TRADITIONS.

Yorkshire Legends and Traditions, as told by her Ancient Chroniclers, her Poets, and Journalists. By the Rev. Thos. Parkinson, F.R.Hist.S., &c. (London: Elliot Stock, 1888.)

LEGENDARY LORE has its interest if not its value to the anthropologist as well as to the philologist. It sometimes happens that a word has given rise to a legend, and that the existence of a legend or tradition indicates identity of race, or a common origin of two widely separated peoples. The science of philology in particular welcomes the data in legends and traditions faithfully given in the vernacular, and undoubtedly affords in its turn a scientific explanation of the origin or meaning of some of them.

The limitation in the title of the present work does no small injustice to the subject, and to the qualifications of the author for treating it, as it excludes many of the most interesting, most local, and most characteristic of Yorkshire legends and traditions, which must be well known to so true a Yorkshireman as the Rev. Thos. Parkinson. This, however, is only a first instalment or "wainload of the marvellous from this county of broad acres," and as such is acceptable. It would be well if the author were to give references to all the principal sources of these legends, as some of them are found in more than one shape, and different versions of the same story sometimes present details which identify the legend with a third legend found perhaps in a distant locality, or with more than one such, thereby proving a still more remote common origin. We will presently exemplify this in the Handale legend. Our author has grouped his materials under nine heads: legends and traditions connected with the early history of Yorkshire; those of abbeys and monastic life; of Satanic agency; Barguest and ghost legends; Mother Shipton; dragons and serpents; battle-fields; legends of wells, lakes, &c.; and miscellaneous legends. The name of *Eboracum*, or York, has proved a fertile source of legends, several of which are collected in the opening chapter; its true origin, not being scientifically demonstrable, is, as our author justly observes, "buried in obscurity." Of the legends connected with the coming of the Danes, that of "Buern the Busecarle" (pp. 10-14), taken from the translation in the "Church Historians of England" (by the Rev. Jos. Stephenson) of the Anglo-Norman "Metrical Chronicle" of Geoffrey Gaimar, written in Stephen's reign, is of historic interest, and receives further elucidation and support from the self-evident fact that "Buern Busecarle" is a Scandinavian or Old Norse and not an English name and title. Björn Bús-Karl = "Björn the farmer of the King's estates," or the "Karl" (A.S. ceorl) of the Konungs-bú or royal demesnes, as he is, in fact, described in the legend. It was because he was a Northman that he called in the aid of the Danes, including Northmen, when his wife was dishonoured by King Osbert, as related by Gaimar. Passing by numerous legends, among which that of the death of King Ella, and the probable site of Ellsworth and Ellecroft or Ellecross is interesting, we note (p. 96) that the horn of Ulphus, or Ulfr, a Norseman who, about the time of King Canute, governed in the western part of Deira, is "a portion of the tusk of an elephant, about 3 feet long." The author excites the reader's curiosity by adding that "round the thick end are engraved a number of emblematic figures, in some respects not unlike those found on Egyptian and Assyrian monuments." Surely there must be extant some expert opinion as to the species of elephant, as to the date and nationality of the workmanship, and whether the tusk was brought from the East, already engraved, by the far-roving Northmen—but here our author fails us. The "Filey

Haddock Legend" (p. 121) appeared in Hone's "Table Book," 1838, ii. p. 638, signed "T. C."

We are compelled to pass over much interesting matter, such as the legend of the submerged town in Semerwater (for which see also Barker, "Wensleydale," 1856, p. 239), which is also told of Gormire Lake, of Lough Neagh, and is one of the legends of the Rhine. Gormire Lake is formed on the back of a landslip. The original version of the pretty ballad on the legend of the Troller's Gill (p. 127) and of Billy B.'s adventure (p. 130) is given in Hone's "Table Book," 1838. The article is signed "T. Q. M.," the *nom de plume* of the late Dr. J. H. Dixon in the "Table Book." Also our author's "Wise Woman of Littondale" (p. 134), from the "Table Book," ii. p. 775, signed "T. Q. M.," is one of Dr. Dixon's productions. With regard to the probable site of "Stoknmore" (p. 162) a local tradition identifies the erect column of stone, 11 feet high, known as the "Long Stoop," on Yeadon Moor, as the subject of Mother Shipton's prophecy "then will ravens sit on the cross, and drink as much blood of the nobles as of the commons."

With reference to the Handale legend (p. 168), the version there given is taken from the *Leisure Hour* for May 1878, but that, in its turn, is almost word for word taken from Ord's "History of Cleveland," 1846, p. 283, as related by Mr. Marr, then tenant of Handale farm. Another original version obtained by the present writer from Mr. Robert D. Watson, of Loftus-in-Cleveland, describes the hero as "a *shoemaker* of the name of Scaw" [O.N. Skór, a *shoe*] who "had a suit of clothes made into which he had by some means stitched all over it razor-blades edge outwards," an item which is identical with that given by our author (p. 171) of the slayer of "the dragon of Loschy Wood." Though our author does not include Beowulf among his legends of Yorkshire, we are of opinion that the able demonstration of Mr. Haigh, in his "Anglo-Saxon Sagas," 1861 (which can now be supported by additional facts, overlooked by him, such as the two coins of "Hæreth," found in Northumbria and engraved in Hickes's "Thesaurus," 1705, iii. p. 168), that Cleveland was the scene of the principal event recorded in Beowulf, remains unshaken by the numerous foreign and English commentaries that have since appeared on the subject. We cannot doubt that the "Grendel" destroyed by Beowulf was a religious house at "Grendale, afterwards Handale," as appears by a charter, anno 1133 (Charlton, p. 90), but space forbids doing more than noting the omission. There are some grievous misprints, *e.g.* "bretwalder" for "Bretwalda" (p. 11), "Worsaal" for "Worsaae" (p. 221), "Upsalier" for "Upsalir" (p. 222).

Among the miscellaneous legends is one called "Swine Harrie" (p. 219) apparently belonging to deer-stealing days, and found in various forms. It appeared in Hone's "Table Book," 1838, ii. p. 722. The thief in carrying his burden home slips in crossing a rock or wall, and is hung by the cord. It should, however, be observed that "Hanging" is a common epithet in the Pennine Hills, *e.g.* "Hanging Stones." *Apropos* of this legend "there is a crag on Embsay Moor called 'Deer Gallows,' and it is said a deer was once hanged there. There is a deep crevasse in the rock becoming narrower toward the bottom, and—the story goes—a deer once fell down and caught with its horns across, and so was hanged" (J. J. Wilkinson). "Gallas" or "gallowses" in the dialect means "braces." The name "hanging" as applied to rocks alludes to some physical feature, but may have localized the legend.

Among the excluded legends we may mention the pretty legend of the "Walling in the Cuckoo," by "t' Hoastik Carles" (the Austwick Carles) and "the funny one of Wengby," "Meal Ark Spring," "Hobthrush Hall," "Simon Amangus," and many others. The legend of "Wallin' in t' Cuckoo" has a wide range, and is told of various villages in the Northern counties. We have heard it in Borrowdale. It is told of Austwick, near Settle, that, seeing a cuckoo in a tree, the carles began to build a wall round it to keep it, and its consequent, the summer, always there, and they were very much astonished when it flew away.

There is another legend of Austwick:—

> "T' Austwick Carles cried 'Whittle ta t' tree,'
> Lifted t' bull ower t' yet, an t' pig inta t' stee."

"There was only one 'whittle' or butcher's knife in Austwick, and when anyone wanted it he went to the tree in the middle of the village in which it was kept stuck. If it were not there, he cried 'Whittle ta t' tree!' three times, and whoever had it was bound to bring it." In the glossary to "Studies in Nidderdale," 1882, p. 291, occurs the article "Wittaled. 'Ah've gittan fas'en'd ta t'sod, if ah aint gittan *wittaled* ta t'tree.'—*Nid. Al.*, 1880. *Wel.* Gwydaw, *to grow woody;* gwyden, a *tree;* gwyddawl, rudimental; so 'wittaled' means rooted to the tree so as to form part of its wood, grafted." Here, the legend evidently takes its origin in the similarity of sound of the two words "whittle," a *butcher's knife*, a familiar word, and "wittaled," *grafted*, a forgotten word preserved in the phrase "wittaled ta t'tree." As to lifting the bull over the gate, they were too simple to know that the gate was meant to open (J. J. Wilkinson). These are samples of the excluded but most interesting legends, which will, we hope, find a place in our author's promised second series.

JOSEPH LUCAS.

FOREIGN BIOLOGICAL MEMOIRS.

Translations of Foreign Biological Memoirs. Vol. I. *Memoirs on the Physiology of Nerve, of Muscle, and of the Electrical Organ.* Edited by J. Burdon-Sanderson, M.D., F.R.SS.L. and E. (Oxford: Clarendon Press, 1887.)

THIS volume is the firstfruits of a scheme which was started some years ago. The original intention was to translate and put before English readers as soon as possible after their publication the most important foreign papers on various biological subjects. Owing to various difficulties, the original scheme had to be altered, with the result that the first volume of the proposed series has taken the form of the present book.

Prof. Burdon-Sanderson has in this volume confined himself to that subject in which he himself is especially interested—viz. the physiology of nerve, muscle, and the electrical organ—and has collected and edited the translations of the most important papers which have appeared in the German language during the last five years on this

very difficult and abstruse subject. The book is divided into three parts : viz. Part I. Researches relating to the Law of Contraction, which contains the well-known papers of Tigerstedt, Grützner, and Hering on this subject; Part II. Researches relating to Secondary Electromotive Phenomena, containing papers by Du Bois-Reymond, Hering, Hermann, and Biedermann; Part III. Researches on the Electrical Phenomena of Certain Electrical Fishes, by Du Bois-Reymond. In addition, a short summary of two or three of the most recently published papers on the subjects treated of in this volume is given in the form of an appendix.

The memoirs selected for translation in Parts I. and II. form a group of papers which are most interesting to all those who are anxious to obtain more than a text-book acquaintance with the difficult questions treated of in them. The translations have been made with great care and accuracy, and with a careful attention to style, though naturally the original German construction is more palpable in some than in others; it would, however, be invidious to select any individual memoirs in this respect. The editor is also to be congratulated upon the manner in which the especially difficult German phraseology inherent to the nature of the subject has been rendered into English. Uniformity of translation among the different translators has been fairly well attained. Perhaps the most noticeable discrepancies are in the translation of the words "*Lücke*" and "*Schwelle*." The phenomenon of the "*Lücke*" is called by one translator the phenomenon of the "gap," and by another the phenomenon of the "hiatus"; of the two, "gap" is perhaps preferable. The almost untranslatable word "*Schwelle*" is sometimes rendered as "limen," at other times as "threshold"; of these two, "limen" sounds best. It is also a pity that the editor has not settled whether the opposite pole to the anode ought to be spelt with a "c" or a "k": cathode and kathode are pretty equally distributed throughout this volume. As to the arrangement of the different memoirs, they all follow each other in natural sequence, with the exception of the second and third papers of Tigerstedt, which ought to have been transposed, as the author assumes in No. 2 that No. 3 has already been read.

Not the least prominent part of the work is the preface, in which the editor briefly links together the various memoirs. As it will seem to many that this should be the most important part of the whole book, it is to be regretted that it is not fuller and also more critical; for undoubtedly any collection of translations of foreign memoirs upon a special biological subject would be very much more valued by English readers if the recognized English authority on that subject prefaced the translations with a critical commentary embodying his own views.

Also, as the object of the book is presumably to enable students and physiologists who do not read German easily to understand the present position of the physiology of nerve and muscle without having to refer to the original papers in the German journals, it would have been better to afford more indication as to the nature of the contents of previous papers which are referred to by the authors but have not been included among the translations. This might have been done by the more copious use of footnotes, or by the translation of one or two more papers. Thus in Biedermann's paper the whole argument is so bound up with his previous papers on the heart of the snail and the muscle of the anodon, that it would have been better to translate the three papers rather than only one. If this had been done, the book would have been large enough without Part III. and there would have been no harm in that, for in the first place the physiology and histology of the electrical organ might well be treated of in a separate volume of memoirs, and in the second place, the papers included in Part III. are all by the same author, and can hardly be considered so important as those in Parts I. and II. Thus Du Bois-Reymond's statement as to "irreciprocal conduction" is based upon an error of observation, according to the recent paper of Gotch in the Proceedings of the Royal Society, and is therefore hardly worthy of a place in these memoirs.

The book is essentially of the nature of an experiment, and it is to be hoped that the demand for it will be sufficient to repay the editor for the time and trouble which he has spent in carrying out his task, and to encourage him to bring out a series of similar volumes dealing with a number of the most important of those biological questions which are the subject of controversy at the present time.

OUR BOOK SHELF.

Examples in the Use of Logarithms. By Joseph Wolstenholme, Sc.D. (London: Macmillan and Co., 1888.)

Practical Logarithms and Trigonometry. By J. H. Palmer. (London: Macmillan and Co., 1888.)

THESE are two books for the use of mathematical students from the hands of practical teachers, who may be assumed to be well acquainted with the difficulties met with by students.

The first one consists entirely of rules and their application to examples. The earliest examples are on the extraction of logarithms from tables. Then follow the reductions of $\sqrt{a^2+b^2}$ and $\sqrt{b^2+c^2-2bc\cos A}$, after which come the various solutions of triangles, finally concluding with a lengthy series of examples on the calculation of the parts of tetrahedra when the sides are given. The author's experience has indicated that examples of the latter class are especially useful in teaching the habitual accuracy which it is desirable to attain, and another reason for their introduction is that they afford preliminary practice in the solution of spherical triangles. Such, then, is the first book, and no one will contradict us when we remark that a student who carefully works out the examples given cannot fail to become perfectly familiar with logarithms and their applications.

The range of the other book is a little wider. Beginning with involution and evolution treated arithmetically, and following with geometrical and trigonometrical definitions, the author leads to logarithms and their simpler applications. The aim of the book is to give a thorough practical knowledge of the use of logarithms and the solution of plane triangles and problems in trigonometry. The general plan adopted is first to state a rule, give worked examples, and then to give a number of exercises on each rule, which may be tested by the answers given.

The omission of the proofs of the rules and formulæ renders the book liable to be looked upon as a cram book, but it is apparently intended mainly for the use of those who simply wish to know how to use logarithms

and trigonometry, and to whom proof is of secondary importance.

The exercises given will make both books specially valuable to teachers, for the working of numerous examples is indispensable in the teaching of mathematical subjects.

Elementary Statics. By the Rev. J. B. Lock, M.A. (London: Macmillan and Co., 1888.)

WE gladly welcome another addition to Mr. Lock's excellent series of text-books. To the new terms already introduced by him, another is now added. This is the term "resolute" as a substitution for "resolved part," the argument for the change being that "the idea is so important in the subject that a definite *name* will be found useful." Those who have already become familiar with the older expressions may not be willing to accept the changes, but there can be no doubt that the new expressions are appropriate, and will be of great service to beginners.

The treatment adopted is based upon Newton's laws of motion, the author's opinion being—and we quite agree with him—that this greatly simplifies the subject. The parallelogram of forces is assumed, the student being recommended to postpone the proof until he commences his study of dynamics. The working of examples, as every teacher knows, is the only way to obtain a thorough knowledge of any subject which requires mathematical treatment, and Mr. Lock has fully recognized the importance of this. Typical examples, excellently selected, are worked out at full length, and numerous others are given as exercises. There is also a selection of papers from some of the Oxford and Cambridge examinations. A new departure is the introduction of a short chapter on graphic statics, which we highly approve of. The teaching of this subject has made rapid strides during the last few years, and the methods are so simple, and applicable in cases which would involve laborious calculations, that the introduction of the subject into text-books is very desirable.

The whole subject is made interesting from beginning to end, and the proofs of the various propositions are very simple and clear. We have no doubt that the book will be appreciated by all who have an opportunity of judging of its merits.

Catalogue of the Fossil Reptilia and Amphibia in the British Museum (*Natural History*). Part I., containing the Orders Ornithosauria, Crocodilia, Dinosauria, Squamata, Rhynchocephalia, and Proterosauria. By Richard Lydekker, B.A., F.G.S., &c. (London: Printed by order of the Trustees, 1888.)

THIS work forms a very valuable addition to the series of British Museum Catalogues, and will be welcomed by all palæontologists as giving a full and complete account of the specimens of fossil reptiles in the National Collection, many of which have an especial interest as being the "type-specimens" on which so many classical monographs have been based.

Mr. Lydekker adopts, with some alterations, the classification proposed in 1885 by Cope, with the modifications recently suggested by Baur. The reasons for the changes he has introduced are fully discussed in the introduction.

Full descriptions of the orders, families, genera, and species, are given in most cases, and the book is illustrated by sixty-nine woodcuts, many of which are taken from the works of Marsh, Dollo, and others. The introduction of the names of many of the larger groups which are not represented in the British Museum collection renders the work more complete, and the addition of so much descriptive matter, and of copious references to the bibliography of the subject, also increases its value far beyond that of an ordinary Catalogue.

The History of Australian Exploration. By Ernest Favenc. (Sydney: Turner and Henderson, 1888.)

THE author of this volume does not profess to give a complete history of the exploration of Australia. Much of the work of exploration has been done by private travellers and adventurers; and it is of course impossible that their labours can ever be adequately recorded. For the fulfilment of such a task the co-operation of hundreds of old colonists would be necessary; and the work, when completed, would not only fill many volumes, but, as Mr. Favenc says, would prove most monotonous reading. He has therefore confined his attention to public expeditions, dividing his subject into two distinct parts—land exploration and maritime exploration. His narrative covers a period of one hundred years—from 1788 to 1888. The book is issued under the auspices of the Governments of the Australian Colonies, and it is in every way worthy of this distinction. Mr. Favenc has invariably gone to the best sources for information, and has produced a record which is not only trustworthy, but full of interest. The value of the book is considerably increased by several maps and facsimiles.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Protest in *The Nineteenth Century*.

THE present age is eminently a sensational one. Everybody deals in superlatives and universals. Morning and evening the newspaper bills vie with each other in appealing to that particular form of curiosity which feeds upon alarms. Our civilization is declared to be altogether wrong. Dr. Pangloss's doctrine is reversed—nothing that is is right. We are incessantly invited to take stock of our arrangements political and social, and treated to denouncements of almost every detail of them. We are too serious, too frivolous, a prey to panics, stolidly blind to dangers, distrustful, credulous. To crown all, what was fondly supposed to be one of the greatest of modern improvements is roundly declared to be a sham; to be worse—a lure to destruction, mental and physical. Loud were the pæans sung some forty years ago over the then new system of competitive examinations which so vexed the soul of the author of "Gryll Grange." Now we are assured that the whole examinational system is utterly stupid, and, in effect, that it were better at once ended than in any way mended.

But literary rhetoric, however brilliant, in these days produces but a momentary impression. We have so much of it that we have come to regard it with the contempt bred of over-familiarity. After the first shock of delight or astonishment has passed off, we begin to look for the facts and criticize the logic. Sweeping phrases, sounding invective, the vigorous style in general, cease to convince. There is too much of the scientific spirit abroad for the roar of the old lions or of the young lions to cause more than a passing alarm. Denunciation is always easy, though not, of course, of the forcible and brilliant kind with which Prof. Freeman and Prof. Harrison have made us familiar, perhaps a thought too familiar. I shall look forward with interest, and with the certainty of some instruction, to the statement which will, no doubt, be forthcoming of the facts the *Nineteenth Century's* protest is based upon, but as a competitive examinationist I look forward to it without anxiety.

Meanwhile, I venture to offer one or two remarks upon a single sentence in the protest. "Again and again," it is said (p. 620), "brilliant young men once full of early promise go down from the Universities as the great prize-winners, and do little or nothing in the after years." The reason, it is added, is that "they have lost their mental life before they are five-and-twenty"; in other words, that the examinational system, *quâ* examinational, has killed in them the love of knowledge by that age—a sad fact enough, if true.

But is it true? Brilliance of parts is not always, I am almost inclined to assert not commonly, accompanied by a disinterested love of knowledge, though often enough by ambition, which is a very different thing; nor, unfortunately, is a love of knowledge always associated with the capacity to gratify it. To many men, again, opportunities fail, or health, or energy of character, or perseverance, or the means enabling them to wait for success in the career chosen, or, lastly, circumstances may have compelled them to adopt an unsuitable career, and so their intellectual lives are wrecked. It is only in respect of the residue remaining after elimination of these cases that the reproaches addressed to the examinational system are capable of being justified. What proportion that residue may bear to the totality of brilliant failures it may be difficult to determine. My impression is that it is a very small one. At any rate, it is so in the University to which I belong—the University of London. So large a proportion of the men who have taken high degrees at that University have in after life fully maintained, to say the least, the distinction of their University record, that the failure of the residue—if such failure there be—may be justly ascribed to causes of the nature above indicated rather than to any ill effect of the examinational system. The assertion may easily be verified by reference to the Honours Lists, more especially in the Faculties of Science and Medicine. I mention these Faculties because it is much easier to trace the after life of graduates in them than in the other Faculties. But on looking over the list of M.A. medallists, I do not find a single name which suggests any lack of after-life response to earlier promise.

Finally, on turning to the University record of many, probably of most, of the eminent men of the day, the very reverse of the alleged disparity between promise and performance upon which the protest is based will be found to exist.

I am, for my part, fully convinced after several years' daily familiarity with the working of a purely examinational system, that in examinations we have the best means yet devised of testing the general ability and attainments of young men and women. And I have shown above that competition does not produce any of the evil results complained of in the protest. On the contrary, I believe it to be in most cases—but certainly not in all—a most useful discipline.

But I have no faith whatever either in piecemeal examinations, or in examinations in technical or special subjects, or in mere manipulative matters. I admit, too, that nothing like sufficient attention is paid to the progressive improvement of examinations in accordance with the advance and increasing volume of knowledge. In particular, the range of optional subjects at higher examinations should be greatly extended, that the test applied to each candidate may better correspond with his opportunities and with his mental structure. Above all, the tendency which unfortunately exists to increase beyond measure the difficulty of examinations requires to be carefully guarded against. Too highly pitched syllabuses necessarily involve a low standard of performance, with the result that the successful candidate and the public are equally deceived.

F. VICTOR DICKINS.

Burlington Gardens, November 6.

Gresham College.

THE communication of Mr. R. D. Roberts states that the article of Prof. Ray Lankester "is based entirely upon a misapprehension as to the purpose and function of the London Society for the Extension of University Teaching and its position with regard to Gresham College."

I beg to be allowed to state that I can indorse Prof. Ray Lankester's statements with regard to the London Colleges. It is nine years since my connection with King's College ceased, but for nine years I was a lecturer in the Evening Class Department of the College. I know that the College staff, often at great personal sacrifice on the part of some of its members, threw such energy into the teaching of evening classes that their efforts can best be described as thoroughly educational in the highest sense. The number of lectures in the winter courses were twenty-five to thirty, in the summer ten. They were, as a rule, as complete and advanced as similar courses in the Universities, some of them more complete than such courses elsewhere.

At the time when the Society for the Extension of University Teaching was first established, it appeared to me to be a superfluous and mischievous institution. The leading idea which it communicated to the public by very extensive advertisements and reports of meetings was, that there was no such form of education in London, and that the teachers subsidized by the Society were bringing enlightenment from the Universities of Oxford and Cambridge. For several years there were courses consisting of only three or four lectures, delivered in districts widely separated, as, for instance, in Mile End, Kensington, and Dulwich, while a long course consisted of only ten lectures. There was no curriculum in any one centre in either arts or science. The courses of lectures were not even grouped into Departments or Faculties, such as modern languages and literature, Latin and Greek, ancient history and archæology, pure and applied mathematics, experimental science, or biological science. Desultory instruction, not education, appeared to be the object of the Society. The lecturers were, as a rule, qualified for the duties they undertook; some were eminent men, even of the highest eminence; but I do know that others from the Universities should certainly not have been intrusted with the duty of public lecturers until they had undergone an additional term of instruction and training of at least three to five years as assistants to Professors. The Society provided employment for a number of unemployed graduates from Oxford and Cambridge; and at the time, no doubt, it was considered politic and conciliatory to make an assumption of carrying culture to the masses. The young men were willing to take up such duties, for they gained opportunities for practice in the art of teaching which led to possibilities in the way of promotion. There is little doubt that the Society has improved latterly, and it may or may not deserve to be supported by public subscriptions; but it would be a monstrous injustice to King's and University Colleges to place the funds of Gresham College in the hands of this Society. The injustice would be the greater in the case of King's College, because, as I understand, University College has discontinued its Evening Class Department; but for at least twenty years before this London Society for the Extension of University Teaching was in existence or thought of, the staff of King's College, without endowment, were teaching by night as well as by day, and with inadequate remuneration doing more than fulfilling the intentions of Sir Thomas Gresham. The City clerks, engineers, and manufacturers left their places of business to attend these lectures, and obtained sound theoretical and practical instruction in art and science, ancient and modern literature and languages. I have in mind many who have risen to distinction; and there are, no doubt, thousands who are ready to acknowledge the benefit they derived from the evening classes of King's College.

I doubt whether these facts were placed before Mr. Goschen on the occasion when he made his speech on the subject of this Society and Gresham College. It seems to me that the matter should be put before him and all others concerned in a true and proper light, and without partiality.

In conclusion, I will state it as my carefully-considered and deliberate opinion that the Lecture Society called the London Society for the Extension of University Teaching has done no educational work which for extent or solidity is worth consideration in comparison with that of King's and University Colleges.

W. N. HARTLEY.

Royal College of Science, Dublin, November 9.

Divergent Evolution.

SOME of your readers may possibly remember a paper of mine on "The Variation of Species as related to their Geographical Distribution," which appeared in NATURE, vol. vi. p. 222. About the same time I prepared a paper on "Diversity of Evolution under One Set of External Conditions," which was published in the Linnean Society's Journal—Zoology, vol. xi. pp. 496–505. I refer to these papers simply to say that the problems there discussed have occupied my attention more or less ever since.

Part of my paper relates to the subject discussed by Mr. Romanes in his paper on "Physiological Selection"; but as it has been independently worked out, I believe it will be of interest to all who have followed the discussion on the "Origin of Species." The abstract of Mr. Romanes's paper given in NATURE, vol. xxxiv. pp. 314, 336, 362, did not come into my hands till the following January, when my theory of "Divergent Evolution through Cumulative Segregation" was, for the most part, written out in its present form. Since then, and with reference to the discussion on "Physiological Selection," I have worked out the algebraic formulæ given in the fifth chapter, and have introduced explanations of the same.

My "segregate fecundity" and Mr. Romanes's "physiological selection" are the same principle; and our theories still further correspond in that we both insist on the prevention of intercrossing as a necessary condition for divergent evolution. This conclusion was reached by me through investigations made many years ago, and was maintained in my paper on "Diversity of Evolution under One Set of External Conditions," and in still stronger language in articles in the *Chrysanthemum* (Yokohama), January 1883, and in the *Chinese Recorder* (Shanghai), July 1885. In the first of these papers I used the word "separation" to indicate the phase of the principle that results from migration; but for a fuller discussion of the subject I found it necessary to introduce "segregation" as the more significant term; and in the second paper I maintain that "While external conditions have power to winnow out whatever forms are least fitted to survive, there will usually remain a number of varieties equally fitted to survive; and that, through the law of segregation constantly operating, ... these varieties continue to diverge till separate species are fully established, though the conditions are the same throughout the whole area occupied by the diverging forms;" and in the third paper I said, "I am prepared to show that there is a law of segregation rising out of the very nature of organic activities, bringing together those similarly endowed," and causing "the division of the survivors of one stock, occupying one country, into forms differing more and more widely from each other." Since then, my nomenclature of the subject has been worked out with that word as the central symbol of my theory. It is therefore a pleasure to find that Mr. Romanes uses the same word to express the same general idea, giving to his theory the alternate name of "segregation of the fit" (Linnean Society's Journ.—Zool., vol. xix. pp. 354, 395), and in one place at least describing it as "physiological segregation" (see letter on "Physiological Selection," NATURE, vol. xxxiv. p. 408).

As I have explained in chapter iv., I at first thought of using "physiological segregation" in place of "industrial segregation," but finally concluded that it was a term of such wide significance that it could not be well used as the name of any one kind of segregation, while at the same time it was not broad enough to serve as a general term for all kinds. I therefore greatly prefer the term "segregation of the fit." I would, however, so define it as to cover all forms of segregation.

Though our use of this fundamental word is undoubtedly due to our having the same general truth to express, several divergences appear in the development of our respective theories, tending, we may hope, to a fuller elucidation of the subject.

26 Concession, Osaka, Japan. JOHN T. GULICK.

Alpine Haze.

THE peculiar haze mentioned by Prof. Tyndall is no doubt identical with what is commonly met with in some parts of the Mediterranean. During the hottest and driest weather of the summer, and when no wind is blowing, perfectly horizontal strata of haze can be seen occupying the Gulf of Naples. The peaks of the Sorrentine Mountains, with Solara of Capri, Ischia, Vesuvius, Camaldoli, &c., stand out above this haze. The height of the strata rarely reaches 2000 feet, and is more often about 1500 feet. The same facts that led Prof. Tyndall to consider it other than water vapour, and of micro-organic nature, had produced in my mind similar conclusions. This haze, when looked at near the sea, has often a beautiful pink tint, due, no doubt, to a complementary effect from the sea-water colour, as the colour is more marked on the limestone rocks, where the white sea-bottom makes the water look much greener When, however, the observer is cut off from a view of the green sea for some time, the haze has then a light buff colour. The opacity of this haze is so great as sometimes to resemble a slight London fog.

Anyone who would count the number and study the characters of the organisms and other solid contents of the air here at different times would soon settle the question what this phenomenon is due to, and whether there is any truth in the old *blight*. H. J. JOHNSTON-LAVIS.

Naples, November 4.

The Astronomical Observatory of Pekin.

IN your number of November 8 (p. 46), you gave an account of a lecture by Mr. S. M. Russell, of Pekin, on the instruments in the old Observatory there. May I mention that the late Alex. Wylie, about nine or ten years ago, published a full account of them (with illustrations) in the "Travaux de la 3me Session du Congrès International des Orientalistes," vol. ii. Having had my attention drawn to them by some photographs kindly sent me by Mr. Russell, I pointed out the scientific interest of Ko Show-King's instruments (which anticipated the ideas of Tycho Brahe by three hundred years), in a paper published in the Proceedings of the Royal Irish Academy, vol. iii., 1881, and in *Copernicus*, vol. i. J. L. E. DREYER.

Armagh Observatory, November 12.

AN HISTORICAL AND DESCRIPTIVE LIST OF SOME DOUBLE STARS SUSPECTED TO VARY IN LIGHT.

THE light-changes of double stars are, for the most part, of an intermittent character. Unmistakable at one epoch, they may completely evade detection at another. Hence observations of them which, by the nature of the case, cannot be repeated are apt to incur discredit for lack of confirmation. They should, on the contrary, if properly authenticated, be carefully borne in mind, as testifying to an incident in the history of the stars they refer to which, however apparently isolated, must be extremely liable to recur. We have therefore thought that it would be useful to put together, as concisely as possible, a few facts bearing on the supposed variability of some stars which we may reasonably consider to be physically double, referring those of our readers who desire fuller information on the subject to the original authorities we shall cite for their convenience.

γ Virginis = Σ 1670.—The first observation is by Bradley in 1718. The components, normally of the third magnitude, were regarded as equal by all observers until W. Struve, May 3, 1818, noticed the preceding star as slightly the fainter. It continued so for several years; the difference was obliterated from 1825–31, and reversed, doubtfully 1832–33, certainly in 1834 ("Mensuræ Micrometricæ," pp. lxxii. 4). O. Struve's observations, 1840–74, showed decided variability in a double period, oscillations of half a magnitude in a few days being superposed upon a fluctuation extending over many years. An investigation of the law of change, begun in 1851, led to no result, owing to the low altitude of these stars at Pulkowa ("Obs. de Poulkova," ix. 122). Dawes found them equal, 1840–47; but each alternately about a quarter of a magnitude brighter than the other, 1847–54 (Memoirs R. Astr. Soc., xxxv. 217–19). Similar swayings of lustre were constantly apparent to Dembowski (*Astr. Nach.*, Nos. 1111, 1185, 1979). Each star is given as of 3·5 magnitude (combined 2·8) in the "Harvard Photometry" (see also "Harvard Annals," xiv. 454). Gould assigns to them the combined magnitude of 3·1, Pritchard of 2·67; Gore thought them nearer to the second than to the third magnitude, April 5, 1883 ("Cat. of Suspected Variables," p. 362). (The combined magnitude of two third magnitude stars is 2·25.) Owing to their uncertainty of shining, the angle has often been reversed in measuring these stars. They are of a pale yellow colour, and show a spectrum of the Sirian type. They revolve in a highly eccentric orbit in a period of 180 years, and emit fully sixteen times as much light proportionately to their mass, as the sun.

44 (*i*) Boötis = Σ 1909.—On June 16, 1819, Struve noted a difference of two magnitudes between the components; of one invariably 1822–33, but of only half a magnitude 1833–38. Argelander found them exactly equal, June 6, 1830 ("Mens. Microm.," p. lxxii.). To Dawes, in April 1841, the attendant star seemed a shade brighter than its primary, which was rated as of fifth magnitude (Mems. R. A. Soc., xxxv. 232). Dunér's observations at Lund, 1868–75, confirm their relative variability, causing the disparity between them to range from 0·4 to 1·3 magnitude; and he points out that they appeared to Herschel consider-

ably unequal in 1781, but perfectly matched in 1787. Both stars were yellow in 1875, but the tint of the smaller was at times less deep than at others (" Mésures Microm.," 1876, p. 74). Admiral Smyth marked it as "lucid gray" in 1842; Webb and Secchi respectively found it blue in 1850 and 1859; Webb and Engelmann reddish in 1856 and 1865. The principal star has often been considered as pure white. The spectrum belongs to Class I. The photographic magnitudes of the pair, as determined at Paris in 1886, are 5·3 and 6. Engelmann concluded the smaller component to vary from magnitude 5 to 7, the larger from 5 to 6 (*Astr. Nach.*, No. 1676). They revolve in a period of 261 years, the plane of their orbit passing nearly through the sun. The periastron passage was in 1783. They possess at least four times the solar luminous intensity.

δ Cygni = Σ 2579.—The chief star remains steadily of the third magnitude; its companion varies probably from the seventh to about the ninth. Discovered by Herschel in 1783, it was invisible to him in 1802 and 1804, as well as to his son in 1823, and to South and Gambart, under exceptionally favourable conditions, in 1825 (Phil. Trans., cxiv. 339, cxvi. 376). Struve re-detected it in 1826, since when it has been continuously observed. The fact of its variability has even been doubted (Dunér, " Mésures Microm.," 1876, p. 118; Sadler, *Observatory*, ix. 307). Its changes of colour are, however, unquestionable. Struve marked it as ashen gray, 1826–33, but as remarkably red in 1836 (" Mens. Microm.," p. 297). Dawes found it blue, 1839–41; Secchi, red, 1856·62, blue, 1856·98, violet, 1857·53 (Engelmann, *Astr. Nach.*, No. 1676). Dunér saw it always red, except on one occasion, when it seemed olive. The primary is of a greenish white, and exhibits a Sirian spectrum. The period of 415 years attributed to the pair by Behrmann is probably too long; Hind's, of 179 years, is certainly too short. With Behrmann's elements, the light-power relative to mass comes out *one hundred times* that of the sun.

The three couples just described are the only variable double stars of which the orbits have been computed. We shall now mention a few which have so far described arcs too small to serve as the bases for investigations of the complete ellipses.

ζ Boötis = Σ 1865.—The following component was found the brighter by Herschel in 1796, and by Struve, in general, until 1833, when the order was reversed. They were pretty equal 1821–24 (Pickering, "Harvard Annals," xiv. 458). Their alternating fluctuations were confirmed by O. Struve's observations, 1840–63, since when, until 1878, the preceding star had always the advantage (" Obs. de Poulkova," ix. 143). F. Struve estimated their magnitudes at 3·5, 3·9, adding the remark, "Splendor in altera stella est variabilis" (" Mens. Microm.," p. 21). Their photometric magnitudes were determined at Harvard as 4·4, 4·8, the following star being the brighter. Dawes considered them as equal at 4 or 4·5 magnitude in 1847–48, but each star in turn took a slight lead (Mems. R. A. Soc., xxxv. 229). Dunér noted them sometimes as both of fourth, sometimes as of third magnitude, the changes occurring, as a rule, simultaneously (" Mésures Microm.," p. 68). The colour of these stars is white, or yellowish, and their spectrum well marked of the first type. The period of their revolution must be enormously long, and their mass proportionately small.

π Boötis = Σ 1864.—Gilliss's estimates varied from 4 to 5·6 magnitude for one component, from 5 to 6·7 for the other. Schmidt independently suspected fluctuations (Pickering, " Harvard Annals," xiv. 458). As one object, they were ranked by Abdurrahman Sûfi of fifth, by Lalande of sixth, by Harding, Argelander, and Heis of fourth magnitude. Their combined photometric magnitude was determined at Oxford as 4·1, at Harvard as 4·59. Herschel and South marked them in 1822 "nearly equal" (Phil. Trans., cxiv. 199); Admiral Smyth noted a disparity of 2½ magnitudes (" Cycle," p. 411, Chambers's ed.); and Struve found them of 4·9 and 6 (" Mens. Microm.," p. 97), and they were photographed at Paris as of 5 and 6 magnitudes in 1886. They emit white light of the quality of that of Sirius. An arc of about 4° has been described by the companion since 1781.

ε Arietis = Σ 333.—F. Struve had no doubt of the variability of these stars. His estimates of magnitude ranged from 4·5 to 6·5 for one, from 5 to 6·5 for the other component (" Mens. Microm.," pp. lxxii. 1; Pickering, " Harvard Annals," xiv. 434). Struve in 1827, and Dawes in 1845, found them equal; Secchi recorded a difference of one magnitude in 1855 (Engelmann, *Astr. Nach.*, No. 1676). Measured at Harvard as of 5·2 and 5·5 magnitudes, giving combined magnitude 4·6, they together showed to Piazzi and Bode as a fifth, to Harding as a fourth magnitude star. An arc of 10° has been traversed since 1827 (Crossley, "Hand-book of Double Stars," p. 204). The colour of these stars is white.

S (15) Monocerotis = Σ 950 was discovered by Winnecke in 1867 to vary from 4·9 to 5·4 magnitude in a period of 3d. 10h. 38m. (Gore's "Catalogue," No. 41). A ninth magnitude companion at 2″·8 seems to be in very slow orbital revolution. Struve called their colours green and blue (" Mens. Microm.," p. 65). The spectrum is of the first type.

α Piscium = Σ 202.—The magnitudes of these stars were estimated by F. Struve at 2·8 and 3·9 (" Mens. Microm.," p. 43), by O. Struve at 4 and 5 (" Obs. de Poulkova," ix. 17). Harvard determinations brought them out 4·4 and 5·3, but showed relative variability to the extent of half a magnitude. The larger star has been rated from 2·5 to 5·5 magnitude (" Harvard Annals," xiv. 433), and there is scarcely any doubt that the light of both (which is of the Sirian quality) fluctuates to some extent. The colour of the attendant star changes from blue to ashen olive and tawny (Webb, " Celestial Objects," p. 378, 5th ed.; Flammarion, " Cat. des Étoiles Doubles," p. 12). Slow revolution in a plane nearly coincident with the visual line is probable.

OΣ 256 = Lalande 24098, catalogued at Pulkowa in 1853 as 7 and 7·8 magnitudes at 0″·6, but subsequently found to vary respectively from 7 to 7·8, and from 7 to 8 magnitude. Dembowski thrice noted the preceding star as half a magnitude fainter, while four Pulkowa observations, 1842–61, showed it as much brighter than its companion, equality being twice recorded (" Obs. de Poulkova," ix. 327). Their variability was still more plainly evident by the manner of their occultation, as observed by Mr. Tebbutt, August 22, 1887. Three-fourths of their combined light disappeared instantaneously, leaving the semblance of a "blurred ninth magnitude star," representing, nevertheless, the chief component of recent measures, to be extinguished a little later (*Observatory*, x. 391). The stars have described an arc of 17° since 1842 (Crossley, "Hand-book," p. 287). Their spectrum is given by Von Konkoly as doubtfully of the solar type.

38 Geminorum = Σ 982.—Struve observed differences of lustre ranging from 1·5 to 4 magnitudes (" Mens. Microm.," p. lxxiii.). The inference of variability was ratified by Engelmann (*Astr. Nach.*, No. 1676; "Harvard Annals," xiv. 443). The combined magnitude in the "Harvard Photometry" is 4·8. A spectrum of the Sirian type was registered by Vogel in 1883. Colour-fluctuations seem pretty certain in the small star, which has retrograded 18° since 1782. The system has a common proper motion (Crossley, " Hand-book," p. 233).

Σ 1517.—Struve ranked each member of this close pair as of 7·3 magnitude, with slight alternate superiority (" Mens. Microm.," p. 286). Their variability was confirmed by O. Struve, who estimated their magnitudes at 7 and 7·8. A slow retrograde, and a rapid common proper

motion, prove their systemic connection ("Obs. de Poulkova," ix. 106).

The remaining stars on our list are relatively fixed.

Σ 2344.—Magnitudes 8·5 and 10 when first measured by Struve; 8·5 and 12 in 1829, distance = 1″·38. The companion was not again seen until 1835 ("Mens. Microm.," pp. 37, 296). The instability of its light was further attested by its invisibility to Secchi in 1859, to Engelmann in 1865 (Engelmann, *Astr. Nach.*, No. 1674).

Σ 2718.—Components intrinsically equal, but by turns slightly superior. Period of change probably short (Struve, "Mens. Microm.," p. 142).

61 Geminorum.—The brighter component varies from 6 to 7·5 magnitude, the fainter from 9 to seeming extinction (Flammarion, "Les Étoiles," p. 320). The larger star, which is of a deep yellow colour, was recorded by Piazzi as of 7·8, by Heis and Argelander as of sixth magnitude (NATURE, xii. 27; "Harvard Annals," xiv. 445). It was photometrically determined at Harvard as of 5·7 magnitude. Its attendant eluded Webb's search in 1855, Knott's in 1861 and 1871, but was recovered in 1875, when of 12·5 magnitude, by H. Sadler, using a 6½-inch Calver's reflector (Smyth, "Cycle," p. 202; Webb, *Popular Science Review*, xiv. 309). Since these stars are 60″ apart, the probability of their physical connection rests chiefly upon their agreement in exhibiting marked fluctuations of light.

ρ (5) Ophiuchi, described by Admiral Smyth as of 5 and 7·5 magnitudes at 4″; yellow and blue colours ("Cycle," p. 457). But Herschel at the Cape, 1834–37, and Jacob at Madras, 1846, found them exactly equal. Herschel and South in 1824, Secchi in 1856–57, give a difference of one magnitude. Main called them 4 and 4·3, and they were measured at Harvard as 5·3 and 6 magnitudes (Sadler, *Astronomical Register*, xvii. 73; Pickering, "Annals," xiv. 461).

β Scorpii is No. 489 of Gore's "Suspected Variables." F. Struve assigned to the components magnitudes 2 and 4; Pickering, 3 and 5·2, combined, 2·9. J. Herschel found a difference of only one magnitude, Webb of 3½, Gore of 2½ magnitudes (Webb, "Celestial Objects," p. 386; see also NATURE, vol. xxiii. 206, 362). Their colours are yellowish-white and lilac, or (according to Dembowski) ashy green, and they belong to the first spectroscopic class. They are separated by an interval of 14″, but Burnham detected in 1881 a close, faint attendant upon the principal star (Memoirs R. A. Society, xlvii. 193).

θ Serpentis = Σ 2417.—The components are 21″·6 apart, and relatively fixed. Both emit yellowish-white light marked by the Sirian quality of absorption. They were together ranked by Tycho and Bayer as of third magnitude, by Montanari as of fifth, but, with noticeable subsequent brightening (J. Cassini, "Élémens d'Astr.," p. 74). Gould's estimates wavered from 4·1 to 4·6 magnitude, and gave strong evidence of variability in one of the stars ("Uranometria Argentina," p. 322). Gore thinks that its changes may prove to be modelled on those of Algol (Journ. Liverpool Astr. Soc., v. 110). The separate photometric magnitudes registered at Oxford were 3·9 and 4·2; at Harvard, 4·7 and 5·1, where, however, the difference of lustre between the stars was perceived, in 1878, to fluctuate from 0·34 to 1·69 magnitude ("Harvard Annals," xi. 136, xiv. 463). Dunér considered the principal star to be steadily of 4, the companion to vary from 4·2 to 4·7 magnitude ("Mésures Microm.," 1876, p. 112).

Σ 1875 is composed of two white stars at 3″·2, the preceding of about ninth, the following varying from 8·5 to tenth magnitude. Dunér had no doubt of the reality of these changes ("Mésures Microm.," p. 70; Struve, "Mens. Microm.," p. 73).

Atlas Pleiadum = Σ 453.—Found double at 0″79 by Struve in 1827, doubtfully "wedged" in 1830, single with a power of 800 in a clear sky in 1836 ("Mens Microm.," p. 283). As single it has been seen by every subsequent observer, including Burnham, who at intervals during five years searched vainly for the companion detected and always fully believed in by Struve (Mems. R. A. Soc., xliv. 230). But during the passage of the moon across the Pleiades, January 6, 1876, Hartwig recorded the immersion of Atlas as non-instantaneous, a faint remnant surviving the chief part of the light for six-tenths of a second. He did not then know that the star had been marked at Pulkowa "duplex difficillima" (Winnecke, *Astr. Nach.*, No. 2074).

72 Ophiuchi = OΣ 342 is a somewhat similar example. An eighth magnitude companion at 1″·5 was discovered by O. Struve in 1842, but could rarely afterwards be seen, and excited vehement suspicions of pronounced variability ("Pulkowa Catalogue," No. 342). It was last observed at Pulkowa in 1876, and never elsewhere than at Pulkowa except once by Father Secchi at Rome in August 1859 (NATURE, vol. xvi. p. 194). Newcomb could find no trace of it with the Washington 26-inch on two exceptionally fine nights in 1874, nor Hall in 1876. Burnham was equally unsuccessful, and after much fruitless scrutiny recorded the star as "certainly single" in a "first-class night" of August 1880 (Mems. R. A. Soc., xliv. 276). Its spectrum, like that of Atlas in the Pleiades, is conspicuously of the first type.

β Cygni was found by Klein variable from 3·3 to 3·9 magnitude in 1862–63 (*Astr. Nach.*, No. 1663). Espin holds this star to belong to a distinct class of variables (exemplified by 63 Cygni) which change less than one magnitude in a period of several years (*Monthly Notices*, xliii. 271). Webb and Gemmill agreed, in 1881–82, in finding β Cygni much waned from its former brightness (*Astr. Reg.*, xx. 14, 46). The magnitudes of its components were determined at Harvard as 3·1 and 5·2—conjointly, 3. Their photometric difference, however, appeared, from Oxford measures of November 6, 1882, to be only 1·82 magnitude (*Monthly Notices*, xliii. 102). Although 34″ apart, and immovable, their physical union is decisively affirmed by the splendid contrast of their golden and azure tints, to which complementary absorption-spectra correspond (Huggins, Phil. Trans., cliv. 431).

δ Cephei forms, with a "cærulean blue," seventh magnitude companion at 41″, a pair resembling β Cygni (Webb, "Celestial Objects," p. 270). The large star varies regularly from 3·7 to 4·9 magnitude in 5d. 8h. 48m. The maximum of May 6, 1868, was, however, stated by Schmidt to have been barely indicated (*Astr. Nach.*, No. 1745). A minute attendant at 19″ was discovered by Burnham in 1880. The spectrum of the variable is of the solar type. It has virtually *no* proper motion.

α Herculis = Σ 2140 was divided by Maskelyne, August 7, 1777. The variability of the primary, discovered by Herschel in 1795, ranges from 3·1 to 3·9 magnitude in a period fluctuating between 26 and 103 days (Gore's "Variables," No. 129). The attendant is generally rated at the sixth, but Struve found it to change from fifth to seventh magnitude ("Mens. Microm.," p. 97). The colours of the pair are vividly contrasted orange and emerald. The large star shows a magnificent banded spectrum of III.*a* type; the smaller, one analogous to that of the companion of β Cygni in having its absorption almost wholly below the green (Huggins, Phil. Trans., cliv. 432). The common proper motion of the pair carries them in a century over a space nearly equal to the interval separating them (4″·5).

h 1470 = Lalande 38428.—Both stars are supposed to be variable, but have been little observed. Secchi estimated them of 7 and 8 magnitudes in 1856, and measured their distance at 23″·8. Physical relationship is indicated by their "superb" coloration in red and blue ("Catalogo di 1321 Stelle Doppie," p. 117; Webb

"Celestial Objects," p. 294). The spectrum of the red component resembles that of *a* Herculis (Espin, *Astr. Nach.*, No. 2825).

U Cygni = Schjellerup 239*a* was discovered by Knott, in 1871, to vary from 7·7 to below 11 magnitude in a period of 466 days (Gore's "Variables," No. 163). It had previously been remarked by Birmingham for its deep ruby tint (*Astr. Nach.* No. 1809). An attendant at 62″ appears to fluctuate in light from 8 to 8·7 magnitude, in colour from a decided blue to white and reddish (Birmingham, Trans. R. Irish Academy, xxvi. 300; Tarrant, Journ. Liverpool Astr. Soc. vi. 124; *English Mechanic*, xliv. 368; Gemmill, *ibid.*, xlvi. 340). The spectrum of U Cygni is of III.*b* type, but the zones are feeble (Dunér, "Étoiles de la 3e Classe," p. 73).

U Cassiopeiæ = OΣ (App.) 254.—A pair very similar to the preceding. The red star (= Schjellerup 280) varies from 7 to 9, the blue from 8 to 10 magnitudes, both in uncertain periods. Their distance, as measured by Dembowski in 1873, and by Burnham in 1881, is 58″·84 ("Publications of Washburn Observatory," i. 157).

U Puppis = Lalande 14551, found by Espin in 1883 to vary from 6 to 6·8 magnitude in 14d. 0h. 21½m. (*Monthly Notices*, xliii. 432). Burnham resolved it January 28, 1875, into two components, respectively of 6·5 and 8·5 magnitudes at 0″·8 (*Astr. Nach.*, No. 2062). Colour yellowish; spectrum of the solar kind. Proper motion insensible (Sadler, Journ. Liverpool Astr. Soc., v. 142). With a ninth magnitude star at 20″, it forms the fixed pair Σ 1097.

U Tauri is no longer included in lists of variables, the fluctuations noticed by Baxendell, 1865–71, having ceased to be perceptible (Schönfeld, *Jahresbericht*, Mannheim, xl. 51). It is unknown whether they affected one or both of two nearly equal components of 9·7 magnitude (distance 4½″), into which Knott divided the star, December 4, 1867 (Mems. R. A. Soc., xliii. 78). This interesting object has received little or no attention of late.

η Geminorum was discovered by Burnham at Mount Hamilton, November 11, 1881, to be made up of a third and a ninth magnitude star at 0″·96. "A splendid unequal pair," he remarked, "and likely to prove an interesting system" (Mems. R. A. Soc., xlvii. 204). He re-examined it at Dearborn a couple of months later, but we are not aware of any subsequent observation. The variability of *η* Geminorum in a period of 229 days was noticed by Schmidt in 1865. Its greatest extent of one magnitude is rarely attained, and the phases often seem nearly obliterated (Schmidt, *Astr. Nach.*, Nos. 1745, 1988, 2297.) The spectrum is an ill-marked specimen of Class III.*a*.

Y Virginis = Lalande 25086 was found by Schmidt in 1866 to vary from fifth to eighth magnitude in an undetermined period (*Astr. Nach.*, No. 1597). Ptolemy marked it of fifth, Abdurrahman Sûfi as approaching sixth magnitude (Schjellerup, "Description des Étoiles," p. 160). Piazzi catalogued it eighth, but observed it 6·7 and 7 magnitude. It figures in Lalande as of 6·5, in the Madras and Brisbane Catalogues as of sixth magnitude (NATURE, vol. xx. p. 248; "Harvard Annals," xiv. 456). Photometrically determined at Harvard, it came out of 5·7 magnitude. It is the only "Sirian" star showing considerable irregular fluctuations. Its duplicity was detected by Burnham in 1879, the components (0″·48 apart) being estimated as of 6·2 and 6·5 magnitudes. Re-measurements on three nights of 1881 gave no conclusive evidence of change (*Observatory*, iii. 92; Mems. R. A. Soc., xlvii. 190).

A. M. CLERKE.

NOTES.

THE medals of the Royal Society have been this year awarded as follows:—The Copley Medal to Prof. Huxley, for his investigations on the morphology and histology of vertebrate and invertebrate animals; the Rumford Medal to Prof. P. Tacchini for his investigations on the physics of the sun; and the Davy Medal to Mr. W. Crookes, for his investigations on the behaviour of substances under the influence of the electric discharge in a high vacuum. The Royal Medals have, with the approval of Her Majesty, been awarded to Baron Ferdinand von Mueller, for his investigations of the flora of Australia, and to Prof. Osborne Reynolds, for his investigations in mathematical and experimental physics. The medals will be presented at the anniversary meeting on November 30.

FREQUENT application having been made to Mrs. Spottiswoode for copies of papers by her late husband, the President of the Royal Society, she has decided to have them published in a collected form. The collection and editing of the mathematical papers she has intrusted to Mr. R. Tucker.

THE tone of the debate on the Education Estimates last Friday was eminently satisfactory. All who took part in it seemed to recognize that our system of elementary education is still very far from perfection. Sir John Lubbock evidently expressed the general feeling of the House of Commons when he complained that "the great faults of the present system were that it was too bookish and too dry." Mr. Mundella had a good deal to say—and said it well—on the necessity of the education of children being carried on to a much more advanced stage than that at which it now usually stops. "So long as the school life of the child was so short and limited," he said, "it was no use, in his judgment, talking about improved methods or an improved curriculum. So long as a child could enter a factory as a half-timer at ten years of age, or, as was the case in 8000 or 10,000 parishes in England, children were allowed to leave school after passing Standard IV., it did not matter what their curriculum was, or what their methods were, they could have no good results. It was impossible for them to force a number of compulsory subjects into a child who was to follow the ploughtail before he was eleven years of age. In the counties around London it was found that children left school after passing Standard IV., which they generally did about ten. There could not be a greater waste of money than to educate a child up to ten years of age at the expense of the State, and then turn him out into the world, the eventual result being that by the time he had reached thirteen he had forgotten everything he had learnt." After quoting from the report of Mr. Matthew Arnold as to the curriculum in force in Germany, showing that in Hamburg, for instance, there are thirteen obligatory subjects taught in the elementary schools, English being one of the subjects, Mr. Mundella pointed out that in Prussia no child leaves school until he is fourteen. Even after he leaves school, unless he can satisfy the school authorities, he must attend the continuation schools until he reaches sixteen or seventeen years of age.

ADMIRAL MOUCHEZ has received a magnificent set of photographs sent by the French Embassy at Pekin, illustrating Mr. Russell's lecture on the Pekin Observatory, of which we gave an account last week. These photographs will be exhibited in the astronomical museum of the Paris Observatory.

DURING the recent meeting of the British Association at Bath, Mr. G. J. Symons found in the Jenyns Library a manuscript meteorological register of considerable importance—namely, the original daily records kept by the Rev. James Cowe, at Sunbury Vicarage, Middlesex, from 1795 to 1839. It gives barometer, maximum and minimum temperatures, wind, rain, and remarks for each day. This record covers a period respecting which there has been much uncertainty as to both temperature and rainfall, and several meteorologists are of opinion that it should

in some way be rendered generally accessible. The Rev. Leonard Blomefield (formerly Jenyns), to whom the manuscript belonged, has given his consent to its being copied, and an estimate has been obtained of the cost of copying it, and of preparing a lithographed reproduction as a foolscap folio volume of about 530 pages. This can be done, if sixty persons will subscribe a guinea each. As the volume will be one of great interest to all students of meteorology, Mr. Symons should not have much difficulty in obtaining the necessary funds. The sum of £24 has already been promised by various scientific societies and individual subscribers. Not one copy more than those subscribed for will be printed, so that the volume can only be obtained by subscription, and can never become cheap or common.

THE *American Meteorological Journal* for October contains an article by Mr. A. L. Rotch on the organization of the Meteorological service in Russia. Observations were first made there by the Academy of Sciences in 1726, but it was not until 1833 that a regular system was established. Weather telegraphy was begun in 1864, but little was done until 1872, when a daily weather report was commenced, but forecasts are not issued even now. The same number contains a summary of experiments by MM. C. Montigny and F. Dechevrens on the inclination of the wind, in contradistinction to its horizontal motion usually referred to. One interesting fact has come out of these experiments, viz. that the positive inclination (ascent) of the wind increases in proportion as the barometer falls, and *vice versâ*. We regret to see that the closing of the stations on Pike's Peak and Mount Washington, at least for the winter season, is an accomplished fact. The reason is said to be lack of funds, and the impossibility of using the observations for weather predictions. The detailed observations on Pike's Peak are about to be published by Prof. Pickering in the Annals of Harvard College.

THE Pilot Chart of the North Atlantic Ocean for October, shows that the month of September was characterized by the occurrence of three West Indian hurricanes. By far the most notable of these was the great Cuban hurricane of September 1-7, referred to in NATURE, vol. xxxviii. p. 485. The first indications of this disturbance were noticed in the north-east trade-wind belt, east of the 60th meridian, on August 30 and 31. Taking a west by north course, the centre reached the Cuban coast on the night of September 3, spreading devastation on every side. After passing south of Havana on the 5th, a most remarkable feature was developed by a change of direction to the south of west, in violation of the usual law of motion, the storm reaching Mexico, near Vera Cruz, on the 7th. This unusual change of direction was apparently due to the fact that another well-defined storm originated in the same locality about the same time. This storm was central over the Bahamas on the 6th and 7th, while an area of very high barometer prevailed over the middle Atlantic States. There was a marked decrease in the amount of fog along the Transatlantic routes, which is attributed to the fact that only three depressions of any extent passed over those regions during the month. One of these, which developed hurricane force on the 12th in longitude 37°, subsequently passed north of the British Islands, after having crossed the entire ocean.

THE *Russian Gazette* of September 10/22, 1888, announces that the Committee of the Caspian Fisheries has deposited in the Astrakhan branch of the Imperial State Bank the sum of 5000 roubles (about £500) as a prize to be awarded for the discovery of means for the protection of fish against infection, and for the treatment of people suffering from the effects following the consumption of poisonous fish. The prize will be awarded to the person who will accomplish the following: (1) determine by careful analysis the physical and chemical nature of fish poison; (2) investigate by experiments on animals the action of fish poison on the heart, circulation of the blood, digestive organs, and nervous system; (3) determine the rapidity of the absorption of the poison in the digestive channels; (4) ascertain and describe the symptoms which distinguish healthy fish from those in a diseased condition; (5) indicate the measures to be adopted for preserving fish against the development of fish poison in them; (6) discover an antidote for, and the nature of the medical assistance to be rendered in cases of fish poisoning. Both Russian and foreign men of science may compete for the prize. Essays on the subject may be written either in the Russian, Latin, French, English, or German languages, and may be sent in print or manuscript not later than January 1/13, 1893, to the Ministry of Imperial Domains. The non-solution of questions Nos. 4 and 5 of the foregoing questions will not be considered an obstacle to the award of the prize in full, should the other four questions be satisfactorily dealt with. In case it be considered that not one of the essays or works submitted has solved the problem in its most essential parts, the Commission to which the essays will be submitted may award as a secondary prize the sum which shall have accrued as interest during the five years on the sum of 5000 roubles to the author of the work which shall have satisfactorily dealt with a portion of the programme, and which may facilitate a further study of the nature of fish poison.

THE following figures give some idea of the number of animals killed every year in Siberia for the sake of their furs. At the last summer fair of Irbit, which is a market for only a part of the furs exported from Siberia, no less than 3,180,000 furs of squirrels were offered for sale. Of these, 1,018,000 were killed in the forests of Yeniseisk, 455,000 in the Altai Mountains, 200,000 in Yakutsk, and 300,000 in Transbaikalia. A considerable number of the furs of squirrels killed in the last two provinces are exported directly both to China and to Russia, without passing through Irbit. It is worthy of note that this year there was a considerable decrease in the furs of the black squirrel. Only half a million of these furs were brought to the fair, as against more than a million in 1887. Of other furs there were 11,000 blue fox (*Canis lagopus*), from Obdorsk and Berezoff; 140,000 marmots, chiefly from the Altai; 30,000 polecats, 10,000 badgers, 1,300,000 hares, 2000 foxes, and numbers of bears and wolves. The extermination of fur-bearing animals goes on with such rapidity that there are whole regions where hunting has been completely abandoned in consequence of the complete disappearance of the Mustelidæ and the rarity of the squirrel.

THE November number of the *Kew Bulletin* contains valuable papers on Lagos rubber, Liberian coffee at the Straits Settlements, tea oil and cake, Demerara pink root, food grains of India (continued), Yoruba indigo, Trinidad ipecacuanha, treatment of vines in France, huskless barley, and ramie.

THE current number (vol. xxii. New Series, No. 5) of the Journal of the North China Branch of the Royal Asiatic Society is wholly occupied by the first part of a paper, by Mr. A. Henry, on the Chinese names of plants. This instalment contains 565 items. The names are those in colloquial use at Ichang, a town on the Yang-tsze, and the neighbourhood. First we get the Chinese name in Latin letters, then in Chinese characters; these are followed by the scientific name, which is in nearly every case taken from lists compiled at Kew, and by a general description of the plant, and occasionally the use to which it is put by the people. The second part will contain additions to the list, and notes concerning the plant-names that occur in Chinese botanical works.

THE zinc, manganese, and cobalt salts of molybdic acid, H_2MoO_4, have been obtained pure and in fine crystals by M. Coloriano, of Bucharest. Although molybdenum is so interesting an element, forming as it does such a beautifully graduated series of oxides and their corresponding salts, it is rather remarkable that so little is yet known concerning the most important of these latter, the molybdates. On attempting to obtain the zinc, manganese, and cobalt molybdates by double decomposition, using solutions of known strength of the nitrates of the metals in question, and of ammonium molybdate, amorphous precipitates were thrown down, consisting of hydrated acid salts of molybdic acid. On digesting these precipitates for a short time with water, it was found that they became rapidly converted into a mass of crystals, which were eventually separated from the remaining amorphous substances, washed and dried. They were then subjected to analysis, and were found to be normal molybdates, containing water of hydration so firmly combined that the first traces only commence to be expelled at 150° C. and perfect dehydration cannot be effected lower than the temperature of boiling sulphur (447°). Hence it is concluded that the water present is of "constitution." The crystals of zinc molybdate, $ZnMoO_4 . H_2O$ or $MoO_2 \begin{cases} OH \\ O{-}Zn{-}OH \end{cases}$, are transparent and colourless, forming acicular stellar groups. They dissolve but sparingly in water, readily, however, in dilute acids. The manganese salt, $MnMoO_4 . H_2O$, is probably isomorphous with the zinc molybdate just described, the crystals being very similar in form, but distinguished by possessing a bright yellow colour. The cobalt compound, $CoMoO_4 . H_2O$, is also similar in constitution, but the crystals are very much more beautiful. They exhibit a magnificent violet colour, and are almost insoluble in pure water, though readily dissolved by even very dilute acids. All three salts are probably isomorphous, and are similarly attacked by alkalies. An analogous nickel salt was also obtained, the crystals being of precisely the same habit as the three salts above described; but owing to the extreme slowness with which the amorphous acid salt is converted into the crystalline normal one, sufficient quantities have not yet been obtained pure for analysis. From the description given, however, by M. Coloriano, it may be accepted that zinc, manganese, cobalt, and nickel form isomorphous normal molybdates each containing one molecule of water of hydration.

AN interesting paper on "the nephrite question," by Dr. A. B. Meyer, is printed in the *American Anthropologist*. Dr. Meyer is of opinion that too much has been made of the fact that objects of nephrite and jade have been found in districts where these minerals in their natural state have not yet been discovered. It is rash, he thinks, to conclude that the objects must have been brought from a great distance. Prehistoric men may, he suggests, have found nephrite and jade in places where they have escaped our notice. "It may be that the people of prehistoric times continually sought the valuable material in a way quite different from the one we adopt. That boulders in the rivers formed their main source of supply is proved by the fact that a large number of the hatchets show the boulder characteristics, and they certainly left no stone unturned in their endeavour to find them, while we never think of looking for them in rivers. They may also have searched for still greater finds, the last view being supported by the fact that finds have been made as late as the last century in North Germany, in the sand near Potsdam, at Schwensal, near Merseberg, and at Leipzig, and these were evidently nephrite boulders of the North German diluviums. The remarkable block at Leipzig weighed over 38 kilogrammes; it is looked upon by Prof. Fischer and others as having been accidentally lost at that place, and they think that the raw material is of Asiatic origin. Considering that the block weighed nearly 100 pounds, this is not very likely, and I am of the opinion that this nephrite boulder came from Scandinavia, and that it was transported by ice."

LIEUT. D. BRUUN, of the Danish army, having had a moss dug out in Finderup, in Jutland, has made some interesting discoveries. In the moss were found trunks of oak, beech, and fir trees, from 6 to 30 inches in diameter. The branches had in some cases been cut off, but the bark remained. By the side of one of the oak trunks two earthen vessels were discovered, and near another a third, shaped like an urn. In the latter lay a sandal cut from a piece of leather, with flaps, and leather straps for tying to the ankle, the length of the sandal being 7 inches. It seemed as if the trunks of trees had been placed in a certain position for some purpose or another. About 20 feet further to the south, and at the same depth, viz. 6 feet, a yoke of oak was found, $5\frac{1}{8}$ feet long and 3 inches thick, being fairly cylindrically cut out in the centre. At each end were holes, in one of which remained a strap of leather. Other implements of oak were also found, evidently used for carrying. Some of them seemed part of a wheel. Close to the yoke another earthen urn was discovered, which, like the three referred to, was surrounded with sprigs of heather and bramble. Formerly some horns of bullocks and the skeleton of a man in a fur coating were found in the moss. The various objects are now in the Copenhagen Museum, and are said to date from the early Iron Age.

DURING the past summer a great "kitchen-midden" at Grenaa, in Jutland, was the subject of research by the authorities of the Norse Museum at Copenhagen. It is situated a couple of miles from the sea in the midst of a wood. The layers in the midden were clearly defined, the numerous places of cooking being made conspicuous by ashes and remains of charcoal, together with fragments of coarse pottery. A large quantity of animal remains were found, viz. knuckles and bones, which had been split in twain or crushed and the marrow extracted. There were also many shells of oysters and other mollusks. The bones were those of deer, boar, seal, fox, wolf, dog, swan, and goose, with some of fish. Many flint weapons and implements were found, as well as some of horn and bone. Several of the latter had traces of ornamentation.

WE have received the Report of the Survey of India for the year ending September 30, 1887. During the year, the trigonometrical party has extended the triangulation on the Madras coast 170 miles, this being part of the general scheme to complete the triangulation on the coasts of India and Burmah. The aggregate results of the topographical surveys amounted to 17,510 square miles, and the areas of forests to 34,289 miles. In Basti, close upon 2,000,000 plots were cadastrally surveyed, the extent of each only averaging 0·27 of an acre; in Gorakhpur, in a considerably larger area, less than 1,000,000 plots were surveyed. After a little preliminary difficulty, it was found possible to advantageously employ village natives in this work. Altogether, 4273 square miles were cadastrally surveyed. A new map of Calcutta, on a scale of 50 feet to an inch, has also been undertaken. The longitude determinations have been suspended, but the latitudes of five stations on the meridian of 80° have been completed. Advantage has been taken of the various military operations in Upper Burmah to record additional geographical information. The total number of maps issued amounted to 178,398. At Dehra Dun, photographs of the sun were taken for the Solar Physics Committee, South Kensington, on every available day—in all, sixty-three days being lost. Attempts were also made to photograph the corona by means of stained plates, but their success seems somewhat doubtful. As usual, the Report is accompanied by maps showing the extent of the various operations.

THE Sebastopol Biological Station, under Dr. Sophie Pereyaslavtseva, continues to bring out important biological works. In the last number of the *Bulletin* of the Moscow Society of Naturalists (1888, No. 2), Mrs. Pereyaslavtseva publishes (in French) the first instalment of a most valuable work which she has written in association with Miss Marie Rossiiskaya, on the embryogeny of the Amphipods, being a continuation of her previous studies in the embryogeny of Rotifers. The development of *Gammarus pœcilurus* is described in the first part of the work, and an idea of its detailed character may best be given by mentioning that the various stages of development of that one species are illustrated by no less than one hundred and twenty microscopical sections beautifully printed in colours. Two more representatives of Amphipods (*Caprella* and *Orchestia*) have been studied in the same way, while the lady students who work at Sebastopol under the learned lady-director of the station are now studying other species of Amphipods, and especially of *Gammarus*; so that a complete work on the embryogeny of that important zoological division is expected to be ready by the end of the autumn. For the present, Mrs. Pereyaslavtseva refrains from suggesting general conclusions, but at the end of her monograph she points out that throughout the embryonal development of *Gammarus pœcilurus* the cells of its tissues are endowed with amœboid movements. Those movements are less pronounced in the ectodermic and mesodermic layers, and yet the cells of the former are moving and protruding pseudopods even when the endodermic layer has taken the shape of a fully formed pouch, and its constitutive cells may be considered as epithelium. As to the cells of the mesoderm, they maintain the capacity of both locomotion and overlapping (*chevauchement*) even at very advanced stages of the development of the embryo—that is, until the elaboration of the muscular tissue has been completed. These phenomena have been noticed in all the three genera of Amphipods already studied, and most probably they are common to all Amphipods.

MESSRS. MARION AND CO. send us an account of a "detective camera" which has been planned to meet the requirements of the inexperienced as well as the experienced in photography. It has the appearance of a leather dressing-case or despatch-box, and has the special advantage that the person using it sees the exact picture he is to get on his plate, the same lens giving the image on the screen and taking the negative. Another "detective camera" of which Messrs. Marion and Co. have issued a description is in the form of a book, and can be used secretly, since there is nothing to indicate its real purpose.

IN an article on "Irregular Star Clusters" (NATURE, November 1, p. 13), it was stated, with regard to an apparent member of a scattered group in Ophiuchus, that its position "was found, by the comparison of photographs taken by M. von Gothard in 1886 with Vogel's measures of eighteen years previously, to have changed to the extent of 45″, or at the rate of 2½″ annually (*Astr. Nach.*, No. 2777)." Dr. H. Kreutz, of the Kiel Observatory, writes to us to say that more recent measures of Dr. B. von Engelhardt (*Astr. Nach.*, No. 2859) have proved this to be incorrect. The difference between Gothard's photographs and Vogel's measures was due to an error in Vogel's work.

THE additions to the Zoological Society's Gardens during the past week include two White-tailed Eagles (*Haliœtus albicilla*), British, presented by Mr. R. H. Venables Kyrke; two Short-eared Owls (*Otus brachyotus*), captured in the Red Sea, presented by Captain John Marr; a Little Grebe (*Tachybaptes fluviatilis*), British, presented by Mr. Howard Bunn; two Spotted Ichneumons (*Herpestes nepalensis* ♂♂), an Indian Otter (*Lutra nair* ♂) from India, a Sclavonian Grebe (*Podiceps auritus*), British, deposited; four Knots (*Tringa canutus*), European, purchased.

OUR ASTRONOMICAL COLUMN.

THE TOTAL SOLAR ECLIPSE OF AUGUST 29, 1886.—Part 5 of vol. xviii. of the Annals of the Harvard College Observatory, contains an account by Mr. W. H. Pickering of his expedition to Grenada in 1886 in order to observe the total eclipse of August 29; and some points in his report have recently been commented on by Mr. W. H. Wesley (*Observatory*, October 1888) and Mr. Ranyard (*Knowledge*, November 1888). Mr. Pickering's original plan of work had been a very wide one, and he took out a great variety of instruments with him, but no assistants besides his wife and a lady friend. It was very late in August before he arrived at Grenada, and this circumstance and the frequent obscuration of the sun before totality on the day of the eclipse caused several items of his programme to result in complete failure. The long focus photoheliograph and the actinometer under Mr. Pickering's own superintendence gave no results, but Mrs. Pickering secured three photographs with a couple of short-focus cameras, and Mr. Glean one with a telescope of 4 feet focus. One of Mrs. Pickering's photographs supplies some very curious features in the shape of some very faint extensions of the corona on the western side of the sun. One of these is a prolongation of a bright synclinal mass, and rises in a narrow jet to a height of 48′ from the limb, and then divides into three parts, two falling back towards the sun right and left of the centre ray, which attains a total height of 60′, then to bend over in a precisely similar fashion. Another extension further to the north rises to about the same height, 60′, and then curves downward again.

Mr. Pickering's spectrum photographs afforded little fresh information, but confirmed Prof. Tacchini's observation of "white" prominences; and two of his small coronal photographs were used to give a determination of the brightness of the corona. These gave the total actinic brilliancy of the corona with the surrounding sky as 700 units, or ten times that of the full moon with surrounding sky. But the *intrinsic* actinic brightness of the brightest part of the corona was only 0·03, whilst the average intrinsic brightness of the sky 1° from the sun on a fine day was determined to be 1200 times as great.

COMET 1888 *f* (BARNARD).—Dr. R. Spitaler has computed the following elements and ephemeris for this comet from observations made at Mount Hamilton, October 30, at Vienna, November 2, and at Hamburg, November 5:—

T = 1888 September 10·82914 Berlin M.T.

$$\left.\begin{aligned} \pi &= 65^\circ\ 0'\ 12'' \\ \Omega &= 137\ 34\ 17 \\ \iota &= 55\ 17\ 10 \end{aligned}\right\}\ \text{Mean Eq. 1888·0.}$$

$\log q = 0{\cdot}16873$

Error of middle place (O – C).

$\Delta\lambda \cos\beta = -4''$; $\Delta\beta = 0$.

Ephemeris for Berlin Midnight.

1888.	R.A. h. m. s.	Decl. ° ′	Log Δ.	Log *r*.	Brightness.

GEOGRAPHICAL NOTES.

WE are glad to learn from Denmark that Dr. Nansen has been successful in crossing Greenland. Dr. Nansen, it will be remembered, left the ship in a boat off the south-east coast of Greenland, 65° 2′ N., on July 17. He knew his party had to sail south among the ice for twelve days before they succeeded in landing to the north of Cape Farewell in lat. 61°. As he came out at Godthaab, on the opposite coast, in October, he has taken about three months on the journey, which was made in a line about sixty miles south of that he intended to follow. The section crossed by Dr. Nansen's expedition is in the south and narrow part of Greenland, Nordenskjöld's route having been much farther north, and almost in the centre of the land. Unfortunately, Dr. Nansen just missed the last ship from Greenland to Europe, so that he will have to remain at Godthaab till May next. Until then we must wait for full details.

THE paper read at the first meeting this session of the Royal Geographical Society, on Monday night, was by Mr. H. H. Johnston, H.M. Vice-Consul for the Oil Rivers, on the Niger Delta. The "Oil Rivers," Mr. Johnston said—so called from the fact of their producing the bulk of the palm-oil exported from West Africa—are the main rivers, creeks, and estuaries lying between the eastern boundary of the British colony of Lagos and the northern frontier of the German Protectorate of the Cameroons. They are chiefly branches of the Niger, and form the Niger delta, but some few of them have sources independent of that great stream; although close to the sea-coast, within tidal influence, the estuaries of these rivers are interconnected by a wonderful network of more or less navigable creeks. This system of natural canalization is here and there blocked with vegetable growth, sandbanks, fallen trees, or artificial obstacles constructed by quarrelsome or timid natives; but with a relatively small amount of labour and at a moderate cost, the creeks in places might be deepened and cleared, and inland navigation rendered practicable between Dahome and the Cameroons Protectorate. Mr. Johnston then gave a graphic description of these rivers as they present themselves to one arriving on the coast from Europe. Arriving from Europe by sea, it is generally by the soundings and discoloured appearance of the water that we become aware of the near approach to land, rather than by sighting any part of the shore. When within a few miles of the mouth of one of these rivers, the low coast-line is at first indicated by isolated trees, which appear islets of forest unconnected with each other, and distorted by the mirage of each horizon. Gradually these islets, which are really the loftier trees of the fringe of coast forest, become united in one line of purple green, divided only by the imposing gate of the estuary, for which our ship is bound. The bar of the river may be—as in the case of Old Calabar and Bonny—so deep as to be without danger, or it may be relatively shallow, as at Opobo or Akasa. Once over the bar and within the estuary, we find ourselves surrounded by a lake-like expanse of smooth water, the shores of which are fringed with lofty mangroves with their ghastly white blood-streaked trunks—streaked where the bark has been torn or frayed—and their graceful poplar-like foliage of a sad, dull, yellow-green. Behind the mangroves, however, generally show the dark and dense masses of inland forest, growing where the land has acquired firmness and lies just above the limits of high tide. As far as can be seen from the ship's deck, all and everything that is not yellow water is unvarying mangrove. As you ascend the river further and further from the sea, the mangrove loses its exclusive possession of the shores, even if this possession be not here and there broken by little islets of firm land covered with varied vegetation, and generally the sites of villages. Almost before the water has ceased to be brackish, the Pandanus or screw-pine begins to oust the mangrove, and below its fantastic whorls of spiny leaves the lovely Lissochilus orchids conceal the black mud with their leaves, and rear their stout flower-stems to a height of 6 or 7 feet. As the river is ascended still further, though the banks continue marshy, the now perfectly fresh water enables a varied forest to replace the mangrove and Pandanus, and here perhaps the most extravagant development of vegetation may be seen, recalling past geological epochs rather than the poor and mediocre aspects of Nature at the present time. There is not one prominent kind of tree, but an infinite variety of kinds. There is every type of foliage and every shade of green. At the base of the forest on the water-line grow great Arums of the genus *Cyrtosperma*, with flower spathes of pale green streaked with purple red. Above the Arums gleam out the white bracts of a species of *Mussaenda*, while higher up another *Mussaenda* exhibits huge creamy-white flowers without any bracts at all, and yet another species of this beautiful genus has blossoms of a vivid scarlet. Over the lower branches of the trees hangs a thick green veil of convolvulus, dotted at intervals with large mauve flowers. The Raphia palms are also a characteristic of this river-side forest. Ascending this typical river still further, the marshy banks gradually become firm dry land, and the ground even rises from the water into wooded heights. Gradually the river narrows, and the banks increase in height, and red clay now gives place to outcropping rock. Looking interiorwards beyond the vista of the winding river is the exhilarating prospect of a faint blue range of hills. All influence of the tide has ceased, and the current becomes more rapid. It may be hours, or it may be days or weeks, before we reach the outlying spurs of the first range of hills, the first ascent to the central plateau, over the rapids and falls which mark the change from the interior to the coast region. Here you are out of the forest region of West Africa, in the great park-lands of the interior. Mr. Johnston then went on to describe in detail some of the more important places and districts comprised within the British Protectorate of the Niger Territories.

IN a paper read before the last meeting of the Berlin Geographical Society, Dr. von der Steinen described his second exploration on the Xingu, which began at Rio Janeiro in February 1887, and ended at Cuyaba, the capital of Matto Grosso, on December 31 last. The traveller summed up the main results of his journey thus: the topographical survey of the region through which he passed, numerous physical measurements, a complete grammar of the Bakairi of the Xingu, various vocabularies, and a rich collection of the most varied ethnological objects. During his long residence amongst the Xingu Indians, with whom he was on the most friendly and familiar terms, he was enabled to obtain a deeper insight into the manners and ideas of primitive man in the early stages of his culture than any other traveller. Unfortunately, a chest containing his geological specimens was lost, and many of the photographs were injured.

To the November number of *Petermann's Mitteilungen* Herr von Hesse-Wartegg contributes a paper on Lake Tacoragua, in Northern Venezuela, one of the few fresh-water lakes in South America. The oscillation in the extent of the lake is undoubted, ac-

cording to the writer. Humboldt found it 56 kilometres long, and Herr von Hesse-Wartegg only 49. Yet, while the former estimated the area of the lake at 424 square kilometres, the latter gives it at 587. The author gives many interesting details, not only about the lake, but also about the region in which it is situated. To the same number Dr. O. Krümmel contributes a paper, in which he endeavours to solve the old problem of the Euripus.

THE last supplementary issue (No. 91) of *Petermann's Mitteilungen* contains, according to its title, an account of a journey from Hankow to Soochow, and of journeys in Central and Western China between 1879 and 1881. The contents of this particular paper are misdescribed, for it contains only the record of a journey in 1875 from Shanghai to Hankow on the Yang-tsze, thence by the Han River through the Hupeh, Honan, and Shensi provinces to Lanchow in Kansu, and thence to Soochow, close to the Great Wall and the Mongolian deserts, where Herr Michaelis, the writer, remained for some time, and carried out certain explorations in the neighbourhood. Possibly another part or other parts are to follow, of which there is at present no indication. Herr Michaelis was employed in 1874 as a mining expert by the late Viceroy and General Tso Tsung Tang, who had just then chased the Mahommedan rebels out of the Shensi and Kansu provinces, and was about to begin his famous march to Kashgar. He was to investigate the region both within and without the Great Wall for mineral deposits, and especially for gold. Herr Michaelis met Count Szchenyi and his party in Soochow, and naturally a good deal of the ground he traversed has already been described by Lieut. Kreitner, who was surveyor to the Szchenyi Expedition, in his well-known book, "Im Fernen Osten." The paper is accompanied by three excellent route maps.

MOLECULAR PHYSICS: AN ATTEMPT AT A COMPREHENSIVE DYNAMICAL TREATMENT OF PHYSICAL AND CHEMICAL FORCES.[1]

IV.

§ 16. *Electrical Actions.*

IT follows from the principle of the conservation of energy that the processes which give rise to electrical excitation can themselves be called into play by electrical action.

The heating of a conductor by the passage of an electric current is easily explained on the author's theory that electrical conduction is effected by means of molecular vibrations. The electric spark he considers to be due to the separation of particles of the conductor heated in this manner.

The author explains the Peltier effect in the following manner. Let a closed metallic circuit be formed, consisting of two metals, soldered together at the points I. and II., and suppose the circuit to be traversed by a current flowing through the junction I., from the less easily excited metal A to the more easily excited metal B. The molecules of the metal A will then, by hypothesis, easily be thrown into vibration; the metal A will therefore be more heated than B, and will, moreover, be a worse conductor of heat than B. The heat excited in A at the junction I. will therefore be carried to warm the junction II. in the same direction as the current; it will then accumulate at this junction, for A, being the worse conductor, will carry away less heat from the junction II. than is carried to it through B. The junction II. will therefore be heated, while the junction I. will be cooled.[2]

The direct production of light by electrical action has already been considered in § 14 (October 11, p. 581). It is clear that secondary luminous phenomena may also come into play.

Both chemical combination and decomposition may be effected by means of electrical action. The author selects, as an example of the former, the combination of a mixture of oxygen and hydrogen to form water when traversed by electric sparks, which he considers to be due to the absorption by the molecules of the radiant electrical energy proceeding from the positive pole. The motion of the atoms would be accelerated, and the number of impacts increased, giving rise to a series of phenomena similar to those described in § 8[3] (September 6, p. 460). The internal vibrations of the newly-formed molecule will tend towards a steady state, in which the internal energy is as small as possible. Hydrogen and oxygen will unite to form water, supposing the molecules of the latter to be less electrically sensitive than those of its constituents. We should therefore conclude, from the fact that combination occurs under these circumstances, that water is only very slightly sensitive to electrical excitation, which is in agreement with the observed fact that pure water is an exceedingly bad conductor of electricity.

The decomposing action of electricity is exhibited in electrolytic phenomena. These occur in the inverse order to the chemical actions which serve to produce the current. The action is supposed by the author to take place as follows. The fluid receives electrical energy from the positive electrode, which excites electrical vibrations in the molecules immediately surrounding it. These vibrations are transmitted through the fluid according to the ordinary laws of hydrodynamics, but this would not necessarily give rise to an electric current through the liquid, for an accumulation of electricity may take place even in nonconductors. In consequence of these vibrations, however, the molecular impacts will occur more frequently, and a new steady state will be set up, provided such is possible, in which the internal energy has a smaller value than before. Decomposition will therefore take place if the separate constituents are less sensitive to electrical vibrations than when in combination, as their electrical energy will then be less than that of the compound. One of the constituents will, however, be excited to a greater extent than the other, and the one which is least excited will be attracted more strongly by the anode than the more highly excited one. The latter constituent will not, therefore, move towards the kathode with a definite velocity, but will remain where it is, and re-enter into combination with the opposite constituent of a neighbouring molecule. This would appear at first to be in contradiction with the assumption that the compound is more sensitive to electrical vibrations than its constituents, but the apparent contradiction is explained by the consideration that the internal energy lost during the decomposition of the first molecule must reappear in the form of external energy—that is to say, in the form of heat; and the heat thus set free will supply the electrical energy necessary to cause the recombination. This gives an explanation of the "migration of the ions." From particle to particle during this migration, alternate transformations of electrical energy into heat, and of heat into electrical energy, take place. A certain amount of electrical energy will be lost during the process—namely, the amount transformed into heat during the decomposition of the first molecule, and the heat developed in the solution will raise its temperature to such an extent as to cause a recombination between the products of the decomposition set free at the electrode—a result which is in agreement with observation.[1]

§ 17. *Rotation of the Plane of Polarization.*

One of the principal arguments in favour of Maxwell's electromagnetic theory of light is, that it gives an explanation of the rotation of the plane of polarization by an electric current on the assumption of the existence of molecular vortices. It is therefore of considerable importance to determine how far the author's theory is capable of explaining the same phenomenon. Suppose a right-handed spiral to be wound round the axis of X, proceeding from the origin in the positive direction. A current flowing through the spiral away from the origin will then produce a north pole at the origin and a south pole at the other extremity of the spiral. Let a ray of plane-polarized light traverse the solenoid in the direction of the axis, then every point on the axis will move in a short rectilinear path perpendicular to it. Now an electric current has been defined as consisting in a disturbance of the molecular equilibrium of the conductor, propagated along the conductor with great velocity by radiation from molecule to molecule through the intervening ether. The electrical vibrations may be assumed to take place in the conductor in every direction, as in the case of heat-waves; and, as a special case, a disturbance of equilibrium taking place in a single direction only must give rise to an electric current, so that every motion of the ether in a definite direction must be equivalent to an electric current. Motions of any great extent do not come into consideration, for every disturbance in the equilibrium of the ether must consist in vibrations; but, however small the light-vibrations may be, they must be considered,

[1] A Paper read before the Physico-Economic Society of Königsberg, by Prof. F. Lindemann, on April 5, 1888. Continued from vol. xxxviii. p. 581.

[2] In the original, some confusing misprints occur in this paragraph, viz. p. 38, second line, *besser* should be *schlechter*, and in the third and fourth lines A and B should be interchanged.—G. W. DE T.

[3] Since the oxygen and hydrogen molecules are electrically excited to different degrees, they will attract one another. A hydrogen molecule will therefore impinge upon an oxygen molecule more often than upon another hydrogen molecule, thus increasing the chemical action.

[1] See von Helmholtz's "Wissenschaftliche Abhandlungen," vol. ii. p. 958, *et seq.*

in virtue of previous assumptions, to be extremely large relatively to electrical vibrations. The path described by an ether particle originally lying in the axis must therefore be regarded as an alternating electric current of finite length perpendicular to the axis. It must therefore be a current of varying velocity, the velocity having its maximum value when the particle is crossing the axis, and becoming zero at the extremities of its path. Such a current will be deflected by the north pole of the solenoid with a force proportional to the velocity, and therefore the half-vibration will assume the form of a semicircular arc as in the case of an electric arc deflected by a magnet, the ends of the arc coinciding with the ends of the original rectilinear path. The particle during the second half of the vibrations will be deflected in the opposite direction, and therefore will return along the other half of the circle. The effect of the electric current in the solenoid will therefore be to transform the plane-polarized ray of light into a circularly-polarized ray.[1]

The circular motion of the ether particles will be in the opposite direction to that of the current in the solenoid; the small circular current will therefore correspond to a small magnet with its south pole directed towards the origin. The north pole of the solenoid will therefore attract these circular currents, and diminish the rate of propagation of the wave of light along the axis, as each of the circles will tend to approach the north pole of the solenoid. The effect of this motion, again, will be to produce an induction current in the circle in the opposite direction to the former one, and the circle will come to rest in a new position determined by the condition that these two currents shall be in equilibrium. The induced current will be repelled from the north pole, and all these induced currents will form a second ray circularly polarized in the opposite direction to the former one, and having a greater rate of propagation than the original plane-polarized ray.

To obtain a mathematical representation of these results, suppose that we are looking from the origin along the axis of X with the axis of Y horizontally to the right and the axis of Z vertically upwards. The plane of XY may be taken as the plane of vibration of the incident ray, which will therefore be represented by the expression—

$$y = a \sin \frac{2\pi}{\lambda}(x - vt) = a \sin 2\pi\left(\frac{x}{\lambda} - \frac{t}{\mathrm{T}}\right) \quad . \quad . \ (37)$$

This is equivalent to two opposite circularly-polarized rays of equal wave-length determined by the equations—

$$y_1 = a \sin 2\pi\left(\frac{x}{\lambda} - \frac{t}{\mathrm{T}}\right),$$

$$z_1 = -a \cos 2\pi\left(\frac{x}{\lambda} - \frac{t}{\mathrm{T}}\right);$$

and

$$y_2 = a \sin 2\pi\left(\frac{x}{\lambda} - \frac{t}{\mathrm{T}}\right),$$

$$z_2 = a \cos 2\pi\left(\frac{x}{\lambda} - \frac{t}{\mathrm{T}}\right).$$

Owing to the change in the velocity of propagation, λ will be altered, and therefore also T if the medium is isotropic; so that it will be more accurate to put—

$$y_1 = a \sin 2\pi\left(\frac{x}{\lambda_1} - \frac{t}{\mathrm{T}_1}\right),$$

$$z_1 = -a \cos 2\pi\left(\frac{x}{\lambda_1} - \frac{t}{\mathrm{T}_1}\right);$$

and $\quad . \quad . \quad . \quad . \quad . \ (38)$

$$y_2 = a \sin 2\pi\left(\frac{x}{\lambda_2} - \frac{t}{\mathrm{T}_2}\right),$$

$$z_2 = a \cos 2\pi\left(\frac{x}{\lambda_2} - \frac{t}{\mathrm{T}_2}\right).$$

Since the stationary node of the ray remains unaffected, we shall have—

$$\frac{1}{\lambda_1} + \frac{1}{\lambda_2} = \frac{2}{\lambda},$$

$$\quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \ (39)$$

$$\frac{1}{\mathrm{T}_1} + \frac{1}{\mathrm{T}_2} = \frac{2}{\mathrm{T}}.$$

[1] A circularly-polarized ray will therefore behave like a solenoid, and deflect a magnetic needle, affording an example of a direct action of light upon magnetism.

The electric current, consisting in the circular motion of one of the ether particles, will be of a special kind, as its velocity will be variable, the effect of which will be to increase its self-induction. Any one of these circles will be acted on by the other circles, which are indefinitely near to it, and the resulting attractive and repulsive forces will affect the elastic force of the ether which originally determined the vibrations, so that a current of variable velocity must be considered as equivalent to a series of distinct currents following each other in succession, and having their velocities determined by the corresponding accelerations. To investigate this action, consider the two rectilinear components (38) of each of the circular currents. The induction of any rectilinear element on the parallel elements can be neglected, as the actions on each side of any element will be equal in amount, so that it will only be necessary to consider the vertical component of the induction. This is proportional to the change in dz/dt—that is, to d^2z/dt^2. The elastic force on the point x in the direction $x + dx$ is therefore no longer of the form $\mathrm{P} \,.\, dy/dx$, but of the form $\mathrm{P} \,.\, dy/dx - \mathrm{B} \,.\, d^2z/dt^2$, and therefore the force in the opposite direction obtained by replacing x by $x - dx$ is—

$$\mathrm{P}\frac{dy}{dx} - \mathrm{P}\frac{d^2y}{dx^2} + \mathrm{B}\frac{d^2z}{dx^2} + \mathrm{B}\frac{d^3z}{dxdt^2}.$$

So that the differential equation of the light-vibrations will be—

$$\rho\frac{d^2y}{dt^2} = l\frac{d^2y}{dx^2} - \mathrm{B}\frac{d^3z}{dxdt^2}.$$

This equation will, however, be modified by the action of the molecules on the light-vibrations, and introducing the corresponding term from (6) (August 23, p. 405), we have—

$$\rho\frac{d^2y}{dt^2} = l\frac{d^2y}{dx^2} + 4\pi^2c_1(x_1 - y) - \frac{\mathrm{B}}{2\pi}\frac{d^3z}{dxdt^2} \quad . \quad . \ (40)$$

and similarly—

$$\rho\frac{d^2z}{dt^2} = l\frac{d^2z}{dx^2} + 4\pi^2c_1^1(x_1^1 - z) - \frac{\mathrm{B}}{2\pi}\frac{d^3y}{dxdt^2} \quad . \quad . \ (40a)$$

The action of the molecule is the same along both the axes, so we may put $c_1^1 = c_1$, and $x_1/y = \psi(\mathrm{T}) = x_1^1/z$, where $\psi(\mathrm{T})$ is a known function of T^2 determined from equation (4) (August 23, p. 405).

Both the above equations will be satisfied by the functions y_1 and z_1 of (38), provided—

$$\frac{\mathrm{T}_1^2}{\lambda_1^2} = \frac{\rho}{l} + \frac{c_1}{l}(\psi(\mathrm{T}_1) - 1) + \frac{\mathrm{B}}{l\lambda_1} \quad . \quad . \quad . \quad . \ (41)$$

And y_2 and z_2 will also be solutions of—

$$\frac{\mathrm{T}_2^2}{\lambda_2^2} = \frac{\rho}{l} + \frac{c_1}{l}(\psi(\mathrm{T}_2) - 1) - \frac{\mathrm{B}}{l\lambda_2}. \quad . \quad . \quad (42)$$

The quantities λ_1, λ_2, T_1, T_2, are determined by the four equations (39), (41), and (42).

The two waves (38) give together a new wave determined by the equations—

$$\eta = y_1 + y_2 = 2a \cos \phi \,.\, \sin 2\pi\left(\frac{x}{\lambda} - \frac{t}{\mathrm{T}}\right),$$

$$\quad . \quad . \ (43)$$

$$\zeta = z_1 + z_2 = -2a \sin \phi \,.\, \sin 2\pi\left(\frac{x}{\lambda} - \frac{t}{\mathrm{T}}\right),$$

where $$\phi = \pi\left(\frac{x}{\lambda_2} - \frac{x}{\lambda_1} - \frac{t}{\mathrm{T}_2} + \frac{t}{\mathrm{T}_1}\right).$$

This new vibration will take place in the plane—

$$\eta \sin \phi + \zeta \cos \phi = 0,$$

which makes an angle $-\phi$ with the plane of XY—that is, with the plane of the original vibration.

If, therefore, d be the length of the solenoid, the plane of vibration will be rotated in the positive direction through the angle—

$$\psi = \pi d\left(\frac{1}{\lambda_1} - \frac{1}{\lambda_2}\right) + \pi t\left(\frac{1}{\mathrm{T}_1} - \frac{1}{\mathrm{T}_2}\right).$$

As the plane is determined by the value of $\tan \phi$, this equation shows that as the time increases ψ will oscillate between certain fixed limits, the period of which being equal to $1/\mathrm{T}_1 - 1/\mathrm{T}_2$ will be too small to be observed. For all

practical purposes we may assume $T_1 = T_2$, which will give as the angle of rotation—

$$\psi = \pi d\left(\frac{1}{\lambda_1} - \frac{1}{\lambda_2}\right).$$

The assumption $T_1 = T_2$ is not in exact agreement with the foregoing equations for (41) and (42) give respectively—

$$\frac{T_2}{\lambda_1} = \frac{B}{2lT_1} + \sqrt{\mu_1^2 + \frac{B}{4l^2T_1^2}},$$

$$\frac{T_2}{\lambda_2} = \frac{B}{2lT_2} + \sqrt{\mu_2^2 + \frac{B^2}{4l^2T_2^2}}, \quad \ldots \ldots (45)$$

where μ_1 and μ_2 represent the indices of refraction of the medium for vibrations of the periods T_1 and T_2 respectively.

For $T_1 = T_2$, and therefore $\mu_1 = \mu_2$, it follows that—

$$\psi = \pi d\left(\frac{1}{\lambda_1} - \frac{1}{\lambda_2}\right) = \frac{\pi B d}{lT^2} \quad \ldots \ldots (46)$$

that is to say, the angle of rotation is inversely proportional to the square of the period of vibration, a result which is in approximate agreement with observation.

We may bring this result into still closer agreement with experiment by observing that B itself is a function of T. Now B determines the inductive action of the solenoid on the small circle, and must therefore be the differential of a potential, and therefore inversely proportional to the square of the velocity of light. The latter is, however, not constant in the medium, as it is the reciprocal of the index of refraction, and therefore a known function of T.

We may therefore put—

$$B = \mu^2 C, \; \psi = \pi \frac{Cd}{lT^2}\mu^2 \quad \ldots \ldots (47)$$

where C is a constant. The function μ^2 can be determined as in § 2 (August 23, p. 404). If we take Cauchy's approximate formula—

$$\mu^2 = a_0 + \frac{a_1}{T^2} + \frac{a_2}{T^4} + \ldots$$

we obtain an expression for ψ of exactly the same character as that which Boltzmann deduced from his experimental results.

The direction of the rotation depends upon the relative values of λ_1 and λ_2. For $T_1 = T_2$, (41) and (42) give $1/\lambda_1 > 1/\lambda_2$, and therefore $\psi > 0$. If, however, $T_1 > T_2$, and

$$\mu_i^2 = \frac{\rho}{l} + \frac{c_1}{l}\,(\psi(T_1) - 1),$$

then $\mu_1^2 < \mu_2^2$ for media of normal dispersive power, while for media of anomalous dispersive power $\mu_1^2 > \mu_2^2$, and *vice versâ* for $T_1 < T_2$. Now, it was found that the velocity of propagation, v_1, of the first wave was diminished, while that of the second wave, v_2, was increased, so that $v_2 > v_1$.

The equations (41) and (42) may be written—

$$\frac{1}{v_1^2} = \mu_1^2 + \frac{B}{l\lambda_1},$$

$$\frac{1}{v_2^2} = \mu_2^2 - \frac{B}{l\lambda_2}.$$

Therefore when B is small enough we shall always have $\mu_1 > \mu_2$, and therefore $T_1 > T_2$ in the case of anomalous dispersion, and $T_1 < T_2$ in the case of normal dispersion.

In the latter case—

$$\frac{1}{\lambda_1^2} = \frac{\mu_1^2}{T_1^2} > \frac{1}{\lambda_2^2} = \frac{\mu_2^2}{T_2^2}.$$

But in the former case it may be the reverse. The rotation of the plane of polarization will therefore be generally in the positive direction, being negative only in media of anomalous dispersive power, always supposing that B does not exceed a certain fixed limit. This result is confirmed by the observed fact that the lævo-rotatory substances, chloride of iron, and chromic acid, give anomalous dispersion. According to Kundt,[1] iron is dextro-rotatory in spite of its anomalous dispersion, which may be explained by a large value of B, and, as a matter of fact, the angle of rotation is exceptionally large. Maxwell's theory also led to the result that the angle of rotation is approximately inversely proportional to λ^2, but it gave no explanation of the decomposition of the ray into two circularly-polarized rays. Maxwell starts with the assumption of a circularly-polarized ray, and his λ appears to represent the wave-length of this ray, and is therefore different from the λ of the author. His theory rests on the assumption of the existence of molecular vortices, and therefore his differential equations are not the same as Lindemann's (40) and (40*a*).

It has been suggested that the electric current may possibly produce a structure in the medium, similar to that already existing in crystals which rotate the plane of polarization. Hitherto, however, this hypothesis has not been of much use in explaining the phenomenon, as no explanation has been given of the manner in which the ray is decomposed into two circularly-polarized rays such as occur, for example, in a crystal of quartz. The author endeavours, on the other hand, to explain the action of quartz on the hypothesis of an electro-magnetic effect of the ray of light passing through the crystal. There is, however, a difference between the two phenomena which has to be accounted for—namely, in the crystal the rotation is reversed when the direction of the ray is reversed, so that if the ray passes through the crystal, and returns along its own path, the total rotation is zero, while in the case of the solenoid the effect is to double the angle of rotation. The molecules of quartz must therefore be oppositely related to opposite directions, which seems to suggest that the arrangement may be due to the passage of the ray itself causing electric excitation in the quartz, and this is confirmed by the observed fact that quartz can be electrified by the action of light. Now suppose that the molecules of quartz are unequally susceptible to the electrical action of the ether in different directions, and suppose further that the molecules most sensitive to a ray in the direction of the axis are arranged in a spiral, having for its axis the principal axis of the crystal. Then a ray traversing the crystal in the direction of the axis will successively produce an electrical excitation at every point of this spiral, which will therefore act exactly as if the spiral were a conductor carrying a current. The effect on the ray will therefore be to decompose it into a pair of circularly-polarized rays differing in wave-length and in rate of propagation, and the plane of polarization will therefore be rotated. If the direction of the ray is reversed, the direction of the current in the spiral will be reversed, causing a rotation in the opposite direction.

§ 18. *Paramagnetism and Diamagnetism.*

According to the theory of the rotation of the plane of polarization which was developed in the last paragraph, an electric current traversing a medium excites small molecular currents, each one of which acts like a magnet. These currents as a whole cannot give rise to any magnetic action, since alternate currents flow in opposite directions, but this will not be the case if one set of currents is absorbed by the medium, and not the other, which will happen if one and only one of the wave-lengths λ_1 and λ_2, which together give the wave of length λ, is one of the critical wave-lengths for the molecules of the medium, while the other is not.

The existence of Amperian currents in magnets can be explained in a similar manner. Here the currents cannot be excited by the action of light, but it may be assumed that the molecules, even of rigid bodies, continuously perform small steady vibrations about their positions of equilibrium, and therefore come into collision with the neighbouring molecules on every side, thereby exciting the internal critical vibrations, which are visibly communicated to the ether when the substance attains the temperature of redness.

If such a substance is placed within a solenoid, the light-vibrations in the direction of its axis will remain unaffected, while the perpendicular ones will be decomposed into opposite circular vibrations; and the same thing will happen to the components perpendicular to the axis of vibration in any other direction, the components parallel to the axis remaining unchanged. If one of these currents is absorbed, and the remaining one is in the same direction as the current in the solenoid—that is, with a right-handed rotation—the substance will be paramagnetic, while if the rotation is left-handed the substance will be diamagnetic. In order that a sufficiently large number of vibrations should be absorbed, the substance must have a large number of critical periods, and therefore its spectrum must contain a large number of lines, a result which agrees with the fact that the spectrum of iron contains a larger number of lines than that of any other known element.

[1] *Sitzungsberichte der Berliner Akademie*, February 1888.

Whether a substance will be paramagnetic or diamagnetic will depend, in the first place, on the distribution of lines in its spectrum, and also upon the relative values of T_1 and T_2, calculated from equations (39) to (42), and therefore upon the other molecular constants which determine the relation between the wave-length and the period of vibration. The fact of the magnetic behaviour of a substance being partly determined by the values of these molecular constants would appear to make it impossible to predict its magnetic properties from the nature of its spectrum only. It is clear that, according to the author's theory, similar effects might be produced by mechanical vibrations, as by heat, for any excitation of the molecules to a sufficient extent must give rise to phenomena of the kind described.

The results obtained may be formulated in the following statement :—

If a body is traversed by an electric current in the positive direction, it will give rise to a series of pairs of oppositely-directed currents in the neighbourhood of any molecule, and each of these currents will be equivalent to a luminous vibration of definite wave-length. The body will be paramagnetic, when, in consequence of internal absorption, the excess of the right-handed current over the left-handed one is positive; and it will be diamagnetic if this excess is negative.

When a body is magnetized the internal energy of its molecules is increased, and therefore it will become heated—a result which is in agreement with observation. The magnetic saturation will increase as long as such an increase of internal energy can continue; but the limit of saturation will be attained when the molecular impacts have excited currents of the same kind as those which were absorbed, and of equal intensity.

The author explains permanent magnetism by assuming that the molecules of steel can have internal vibrations more easily excited by molecular impacts in some directions than in others. Suppose the sensitiveness to be very small in the direction of the axes of the molecules and very great in perpendicular directions, then vibrations perpendicular to the axis will be the most easily excited by magnetization, and will be transformed into circular vibrations. The planes of these circles will, in general, be inclined obliquely to the axis, and therefore every molecule will give rise to several circular vibrations in its neighbourhood, and the centres of these circles will lie upon a straight line nearly coinciding with the axis of the molecule. Every such circular vibration will be equivalent to a small magnet with its axis perpendicular to the plane of the circle, and the poles of these magnets lie in a straight line. There is therefore a molecular rotation in the direction indicated by Weber's theory. Again, when the axes of all the molecules have become parallel, there will be more frequent collisions between neighbouring molecules in a direction perpendicular to the axes than in the direction parallel to them. The critical relations will therefore be excited and communicated to the ether, giving rise to circular currents, which will again be partially absorbed. The magnetization will be permanent when the mutual action of the molecules and the ether is a steady one. This stationary motion requires a certain supply of external energy, which is continuously transformed into small vibrations of the molecules about their positions of equilibrium. It is an experimental fact that when this supply of energy is considerably diminished by cooling the magnet to a sufficient extent, the magnetism is greatly weakened.

According to this theory, the amount of light absorbed will be equal to the amount emitted, but the latter will have a different vibration-period from the former, since T may be different from T_1 and T_2, and the critical vibrations most easily excited by the molecular collisions will in general be of different period from those which are most easily absorbed. Therefore rapidly succeeding molecular impacts may give rise to luminous vibrations, the periods of which may be different from those proper to the molecules.

§ 19. *Lorenz's and Maxwell's Electro-dynamic Theories of Light.*

The author observes that he has preferred to base the explanation of electrical phenomena upon those of optics rather than the reverse, because optical phenomena are much more completely understood than electrical phenomena. Lorenz and Maxwell both endeavoured to explain optical by means of electrical phenomena. Lorenz[1] bases his speculations upon the resemblance between the differential equations of the motion of electricity and those which represent vibrations of the ether, which can be made identical by the introduction of certain very small terms. His theory has not been sufficiently developed to admit of its application to the discussion of any definite problem. He comes to the general conclusion that the motions of light consist in electric currents, and that the latter consist essentially in rotatory vibrations of the ether about certain axes. In this point Lorenz's theory presents a certain similarity with that of the author, but in the former no distinction is assumed between the magnitude of electrical and luminous vibrations respectively.

[1] *Poggendorff's Annalen*, vol. cii. 1856.

Maxwell has developed his theory to a much greater extent. He, too, starts from the similarity in the differential equations, which are different from those of Lorenz, and also from the author's. Magnetic and electrical actions at a distance are attributed to the energy of an intervening medium, and explained by the assumption of the existence of a strain in this medium. The assumption of the identity of the electrically excitable intervening medium with the luminiferous ether receives strong confirmation from the fact that the ratio of the electro-magnetic to the electro-static unit of quantity is the same as the velocity of light. Maxwell arrives at the result that electrical as well as luminous vibrations are entirely transverse to the direction of propagation, but he does not obtain any further analogy between electrical and optical phenomena, and his explanation of the electro-magnetic rotation of the plane of polarization involves a series of complicated hypotheses respecting the action between matter and ether. Maxwell expressly excludes the consideration of molecular structure, and supplies its place by the hypothesis of molecular vortices.[1] A further important difference between the two theories is that while the author assumes that the material molecules suck up energy from the ether, Maxwell deduces the repulsive actions between two similarly charged conductors from an accumulation of electricity in the intervening medium, especially in the case of an optical excitation of the medium. He does not appear to have arrived at any definite distinction between electrical and luminous energy.

In the preceding investigations the molecules have always been assumed to be of the same size. If there should be any great difference in the sizes of molecules in the case of different substances, then the difference between optical and electrical phenomena would be entirely relative to the size of the molecules of the body considered, so that an ethereal vibration which would give rise to electrical excitation in one body might produce only optical effects in another. The different behaviour of different substances with regard to light and electricity may perhaps depend partly upon this condition as well as on the values of the critical periods and other molecular constants. An interesting question which arises is, What would be the effect of ether vibrations neither very large nor very small in comparison with the size of a molecule? The author has not suceeded in obtaining any definite answer to this question.

§ 20. *Concluding Observations.*

In concluding the paper the author observes that the only hypothesis which he has made use of is that space is filled with a continuous elastic medium—namely, luminiferous ether, the density of which is so small that it may be neglected in comparison with that of matter. The existence of this is sufficiently established from the known phenomena of light.

It is not found necessary to assume a difference in the elasticity of the ether in crystals in different directions, the existence of a special force of chemical affinity, of electric or magnetic fluids, or of molecular vortices.

Thomson's assumption with respect to the constitution of molecules and their relation to the ether explains the most diverse phenomena of physics and chemistry from a single standpoint—namely, the transference of energy between the molecules and the ether, in obedience at every stage to the law of conservation of energy.

The author then suggests that the theory may possibly provide a means of escape from the conclusion, known as the "Dissipation

[1] Maxwell's "Electricity and Magnetism," Arts. 111, 645, 794, 830, 832. In Art. 111 he says: "I have not been able to make the next step—namely, to account by mechanical considerations for these stresses in the dielectric." In Art. 806 the analogy which the author deduces between a solenoid and a circularly-polarized ray is characterized as faulty on the ground that two opposite circularly polarized rays do not neutralize each other, but produce a plane-polarized ray. The author points out, however, that it is only necessary that the electrical actions should neutralize one another. The simple relation deduced by Maxwell between the specific inductive capacity of a medium and its index of refraction does not follow from the author's hypothesis, and this relation has been shown to be only very roughly true.

of Energy," that the total energy of the universe will ultimately assume the form of uniformly-diffused heat of low temperature.

The attractions between the heavenly bodies must upon this theory be ascribed to their being electrically excited to different extents, and continually sucking up electrical energy from the ether. When, then, any one of them loses heat by radiation, it will take up electrical energy which may be transformed within it into other forms. The sun may thus receive compensation for the light and heat which it emits. In this way it seems quite possible that the universe may really be a conservative system. Indeed, the sun may receive a direct accession of light and heat from the electrical energy diffused throughout space, as this would take place if it receded from some other star with a velocity exceeding by a finite amount the velocity of light. This accession would take place when the relative velocity exceeded a certain value, and its effect would be to diminish this relative velocity until the accession of light or heat ceased, when the velocity would again increase, as in the phenomena of the vacuum tube.

The author considers that this might explain many hitherto unexplained changes going on in the sun, especially as it would necessarily involve the inequality in the intervals from maximum to minimum and from minimum to maximum, which is actually observed. It might also give an explanation of the phenomena of variable stars, as seems suggested by Secchi's observation that all red stars are variable.

The author states that he makes these suggestions with diffidence, as speculation upon cosmical phenomena based upon the limited data at our disposal is apt to be misleading; witness, for example, the limitation to which Weber's law was found to be subject.

He points out that, if Newton's law of gravitation be considered only as a first approximation to the law of attraction between the electrified bodies of the universe, then every case of gravitational attraction, including the weight of terrestrial substances, may be considered as due to electrification. The molecular attractive forces may also be due to the same cause. The differences in the electrical excitation of the molecules of various substances would then play an important part in the phenomena of chemical combination (see footnote to § 16).

The rigidity of a body would then be determined by the differences in the electrification of its molecules. These differences would naturally be determined by external circumstances, and would be greatest in the direction of the normals to the surface.[1]

G. W. DE TUNZELMANN.

[1] The foregoing paper in the original form is itself a very condensed abstract of an extensive research, the author only having a limited amount of space placed at his disposal in the journal in which it was published. This may account for the reasoning, in some parts of the paper, appearing somewhat general and difficult to follow.—G. W. DE T.

LEARNED SOCIETIES IN RUSSIA.

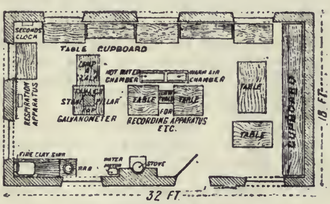
At a recent meeting of the French Geographical Society, M. M. Venukoff read a short paper on the learned Societies of Russia. Besides the Geographical Society, the Army Staff, the Academy of Sciences, and other Government institutions, there are in Russia several learned bodies engaged in the exploration of those countries which are still but little known. Though many of the explorers do not go for geographical purposes properly so called, yet these non-geographical explorers frequently obtain results of the greatest interest to geography. M. M. Venukoff is a member of many of these Societies, and at the outset of his paper he proceeds to name some of his colleagues who have in recent years rendered great service to geography; amongst the members of the Naturalist Society of St. Petersburg, MM. Korotneff, Nicolsky, Lidsky, Yaschenko, and Kouznetoff. The first-named has travelled in the Malay Archipelago, where he has studied chiefly the invertebrate animals, but has at the same time made scientific observations of every kind. In the month of June 1887, he visited the country around Krakatão, where already several little hamlets have sprung up on the site of the town of Anjer, which was destroyed by an earthquake in 1883. These poor huts were surrounded by a luxurious vegetation, while the neighbouring portions of the sea were still covered with pumice-stone and altogether deserted by fish. At Billiton Island the traveller met the interesting tribe of Secasses, the fishermen of their state, who, with rare exceptions, inhabit floating-houses—that is, their junks—and even those among them who possess huts build them on the sea on piles, and never on *terra firma*. They are distinguishable from the Malays by their tall figure, their curly hair, and projecting cheek-bones; finally, strange to say, they almost all stammer. They are a very honest race, gentle, kind, joyous, and hospitable, and it is said that robbery is unknown among them. M. Korotneff describes the tides of the Sunda Sea, which are very complicated, and several other interesting phenomena. M. Venukoff then passes to M. Nicolsky, a famous Russian zoologist, who has pursued his researches in Lake Balkash. He assigns as the cause for the remarkable difference between the fish faunæ of the two districts of Tchui and Ele that the basin of Lake Balkash is separated from the Tchui valley by plateaux and mountains of a very ancient formation. Besides, Balkash is 280 metres above the sea-level, the Sea of Aral is scarcely 50 metres, and the height of the plateaux between Balkash and Tchui is 370 metres at least, and so it is difficult to see how the two great lakes were formerly part of one sea. Balkash, Sassyk-Kul, Ala-Kul, and even Ebi-Nor probably formed, and within the modern epochs, a single vast basin of fresh or slightly brackish water, for their fish fauna is identical with that of our days. In spite of its great extent and its latitude, which is the same as that of Bordeaux and Venice, Lake Balkash freezes every year from the month of November up to the middle of April, and the ice sometimes is as thick as 80 centimetres. A fact worthy of observation is that the steppes which surround the lake vary very much according to their position. Those on the north-west are clayey, and completely bare during the summer, and covered with pools in the spring; those on the south-east are formed of beds of sand, in which there are no pools, but where water is to be found below a certain depth. Thus the desert in the latter case is not so dry as it is to the north and to the west. From the point of view of a zoologist, M. Nicolsky finds that the north and west of Lake Balkash are marked by the presence of jerboas and of larks, whilst at the south of the lake there are numerous reptiles and tortoises; some hares and mice dwell there also, but there are no birds. M. Venukoff does not follow M. Nicolsky into the remainder of his report, as it deals chiefly with the natural sciences; but he remarks that M. Nicolsky shows all the qualities of Humboldt and Mr. Wallace —abundance of well-established facts, and great breadth of view in explaining them. M. Lidsky travelled in Karateghin and in part of Bokhara. Having arrived in the month of June at Schahrisiabz, M. Lidsky wished to journey to Hissar by the Sangardak Hill, but this being prevented by the snows, he was forced to make a detour and enter the valley of the Sourkhan by another route. From this vast prairies stretch away as far as the Oxus, inhabited not by men, but by jackals, for the waters of the Sourkhan flood the plain each year. In rising from this valley, he soon arrived at Garma, and then at Karatag, the summer residence of the Bey of Garma, which is usually hidden from the heat and the fevers which prevail in Garma in the hot season. There, and at Fezabad, M. Lidsky saw fish the skin of which was of exactly the same shade as the water which holds them, and which abounds in clayey soils—that is, of a red colour. Beyond Fezabad the traveller pushed into the high valley of Dachti-Bidona, which is really a plateau separating the basin of the Sourkhâb from that of the Kiafirningan. M. Lidsky describes Karateghin, which is 150 kilometres in length and 50 in breadth, as a fertile country in its lower parts, and thickly covered with forests in the mountainous regions. Unfortunately this oasis is separated from all the neighbouring countries by high peaks, so that the journey from Garma to Samarkand, for example, passes over Mount Pakchif, which is at least 3850 metres above the sea-level. The cold is so great at the top of the mountain that beasts of burden and even men are frequently overcome by it; travellers are often compelled to throw before them long strips of felt, on which they walk—a singular and a very slow and painful mode of progression. In 1877, M. Yaschenko made a journey in Russian Lapland, between Kola and Kandalaschka. According to him the lakes of this region belong to the basin of the White Sea or to that of the Arctic Ocean, and have identical fauna; but the terrestrial animals are not everywhere the same. There are places where bears abound; there are others where the principal enemy of man is the glutton. In latter years the inhabitants have remarked that the reindeer are changing their habits, and are beginning to prefer the forests to the *tundras*, or spaces covered with lichens, which make their favourite food. The reason of this change is to seek a more favourable shelter from the hunters; in the open, whole herds may be taken, but in the forest it is only possible to hunt one or two at a time.

M. Kouznétoff has pursued zoological and physical geography researches on the Sea of Azov. This little basin, of which the length does not exceed 350 kilometres, and its breadth 170 kilometres, and its depth scarcely 14 metres, abounds in fish, and attracts continually to its shores crowds of fishermen. Its water is brackish rather than salt, for its percentage of salt is only 1·19, while that of the Black Sea is 1·75, and the Mediterranean more than 2·3 per cent.; and consequently the real sea-fish are not to be found in the Sea of Azov. *Gourmets*, however, would find that the sturgeon is very numerous here, and has delicious flesh. We can see by this short account that the study of geography is making great strides in Russia. Three years ago, General Tillo, in drawing up his magnetic charts of Eastern Europe, discovered certain anomalies in the distribution of the magnetic elements around Koursk and Kharkov. During the summer of 1887, M. Piltchikoff, Professor at Kharkov, made inquiries into these anomalies, and he has just published a book in which the theory of terrestrial magnetism started by Gauss is developed.

RESEARCH LABORATORY OF THE ROYAL COLLEGE OF PHYSICIANS, EDINBURGH.

FOR some years the question of equipping a research laboratory occupied a very prominent position in the discussions of the Royal College of Physicians, Edinburgh, and last year the Committee appointed by the College was able to throw the plans into a feasible and at the same time thoroughly acceptable shape. Within a very short time suitable premises were acquired, the necessary structural alterations were at once commenced, a Superintendent was appointed, and apparatus was ordered and fittings were put in hand to be ready for use as soon as the building should be prepared for their reception. The premises are well adapted for the purpose for which they were acquired. They consist of a three-storied house, No. 7 Lauriston Lane, near the Royal Infirmary, to which had been added a large detached room in the back court. There are also commodious out-houses and a plot of ground of considerable size at the rear of the building.

The room in the back court is set apart for experimental physiology. It is 32 feet in length, 18 feet in breadth, and 14 feet high, and is well lighted by seven windows, three of which, facing to the west, are fitted with tables for microscopic work.



EXPERIMENTAL ROOM

FIG. 1.

Near the south end of this room is a stone pillar bedded in the ground, so arranged as not to be affected by movements in the room. (There being no thoroughfare in the lane, no disturbance can arise from wheel traffic.) Around it is fixed a table to which the galvanometer wires are attached. The galvanometer is placed on the stone pillar in a glass case with a hinged door, and is always kept ready for use, short wires being carried from the table to the instrument. A hinged lamp table and brass rods over which curtains are hung complete the galvanometer fittings. Work-tables occupy the remainder of the centre of the room. Electrical, time-marking, and other apparatus, tuning-forks, perfusion apparatus, shunts, compensators, constitute the greater part of the instruments in this room. The sink and drainage apparatus in the room may be taken as a type of those throughout the whole house. It consists of a large earthenware sink, on one side of which is a grooved draining-board covered with lead, the grooves all leading to the sink. A swan neck tap supplies the water; to this tap are two nozzles, to one of which is wired a piece of india-rubber tubing, used to connect the Geissler exhaust-pump, and similar apparatus; the other nozzle gives a steady unbroken jet of water three-eighths of an inch in diameter. The wall behind the sink is leaded for about 3 feet up; at the upper part of this are a couple of shelves, the upper one perforated, for draining flasks and bottles, the lower one grooved, and with a gentle slope to carry all moisture to the sink. Below these shelves are a couple of rows of wooden pegs fixed into the wall at an angle of 45. These are very useful for draining all kinds of glass vessels. In the main building in the lower flat is a large entrance lobby, to the left of which is a part of the laboratory assistant's quarters.

A large room on the first floor, set apart for Committee meetings, is used as a library and museum. On the second floor is the chemical room, fitted with a good supply of water and gas. On the top floor are three splendidly-lighted rooms, all of which are devoted to microscopic work. In the south room the apparatus necessary for bacteriological research is collected. Two large projecting roof or dormer windows face east and west respectively. Each is fitted with a table covered with a sheet of plate-glass, on the under surface of which are painted three strips, the first, 4 inches broad, black; then a similar white band, and then a

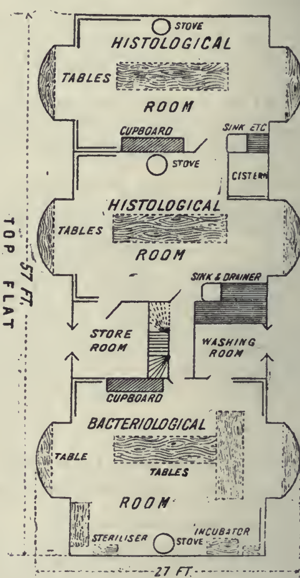


FIG. 2.

broad black band extending to the back of the table. On each side are shelves from the floor for about 5 feet up. These are within reach of anyone sitting at the table. On each side is a drawer $3\frac{1}{2}$ inches deep; but the remainder of the space under the table is left quite open, in order that earthenware jars for the reception of chemicals, washings, and *débris* may be accommodated. On the left side is fitted a rack for test-tubes, and in front and to the right are stands for ordinary histological reagents. Above the level of the table in front are four small shelves, on which are placed covered vessels for clean and dirty slides and cover-glasses. A syphon arrangement for distilled water, a bell-jar with counterpoise running on a brass rod, a Bunsen burner, and a lamp, complete the fittings at this table. One of Browning's microspectroscopes has also been fitted up in this room. Racks, for series of Hesse's tubes, and shelving complete the fittings here; but opening out from it is a small room with a sink and large sloping drainer, at which most of the glass apparatus is washed. The other two rooms in this flat are fitted up for histological work, with window tables, sinks, cupboards, spirit vessels, and shelving, each for two workers. In connection with the histological department, apparatus for micro-photography has been fitted up by Mr. Forgan.

The arrangements for conducting the work are somewhat as follows:—The College has established and will maintain the laboratory for the prosecution of original research. To facilitate such work the Council of the College "appoint a scientific Superintendent, who must devote such portion of his time as may be determined by the Council to the work of the laboratory, where, under the supervision of the Curator and Committee, he shall himself undertake the prosecution of original research, and be prepared to assist, if required to do so, in the work of other investigators. Under like supervision, he shall also be prepared to furnish the Fellows of the College with reports upon such matters as the histology of morbid specimens, and of the chemical and microscopic characters of urines," in which work he is assisted by the resident assistant.

The laboratory is open without fee to Fellows and Members of the College, "to any Licentiate who shall obtain the sanction of the Curator and Committee to use the laboratory for the purpose of scientific research," and "to any medical man or investigator who shall obtain the sanction of the Council of the College, as well as of the Curator and Committee, to use the laboratory for the purpose of scientific research."

The whole of the expense of establishment and maintenance has been and will be defrayed from funds placed at the disposal of the Committee by the Council of the College. Of this, an initial grant of £1000 was made with which to adapt and furnish the house, and buy apparatus, instruments, and chemicals. In addition to this, an annual grant of £650 is made, from which all salaries, rent, and taxes are paid, and stock is kept up. Of these sums, only about £830 of the original £1000, and £600 of the annual grant, were spent during the first twelve months, so that the whole equipment and fittings of the laboratory, together with the current expenses during that period, cost only £1430.

CYCLONES AND CURRENTS.

MR. S. R. ELSON, an experienced pilot of the Hooghly Pilot Service, and author of "The Sailor's East Indian Sky Interpreter," writes as follows with reference to the article on the incurvature of the winds in cyclones, published in NATURE, vol. xxxviii. p. 181:—

So deeply is [the] "old and exploded error of facts," the eight-point theory of storms, rooted in the minds of some, that, ignoring the reiterated warning voice of science, they will have none other. Do they lean towards it because it is so very simple to look at on paper, and so easy of application? I fear that is about the truth of it. So very easy, that Piddington, somewhere in his writings, says of a certain old salt whose ship had been dismasted in a cyclone, that if even a junior P. and O. Company's midshipman had had the handling of his vessel, she would have come through the storm scatheless (the P. and O. midshipman, it must be presumed, having been schooled in Piddington's theory)—a reflection which we, with our more extended knowledge, now perceive was very hard on the old experienced captain. Yet there is the proclaimed peril of using this theory staring mariners sternly in the face.

But there is one more cogent element of trouble and danger besetting the anxious mariner, which, although taken note of in Mr. Pedler's recent Report on the Meteorology of the Bay, is not generally considered when judging, as Piddington used to do, of a shipmaster's proper or improper management of his vessel in a cyclone, and which will probably account for the numbers of vessels, perhaps widely separated before the cyclone came on, which unaccountably get foul of the comparatively small space called the "eye of the storm" as it progresses on its fell course, and so have to bear the brunt of the dreaded rear hurricane wind from south-west or west—that is, the great indraught towards the very centre of the waters in which they float.

This whirling indraught, drift, or set of the sea is on the move long before even the air motion above has gained force enough to impel it, as is so well shown by the westward set at the Hooghly Pilot Station, which usually gets up some time before every cyclone in the Bay, whether far or near. But the worst of it is, when the vessel is out of sight of any fixed object, or the skies are overcast so as to preclude sights being taken, the force and direction of this inset cannot be calculated and allowed for in the dead reckoning as a "course and distance." And it is only after the gale is over, and a sight can be taken, that the captain is very much astonished to find his vessel's position is so far out of her dead reckoning.

I myself, as a pilot, have experienced this perplexity on more than one occasion at the head of the Bay; and, besides, the published records and logs of vessels involved in these storms show this whirling inset of the sea most conclusively.

Mr. Blanford's rules for finding the bearing of the centre of storms are evidently calculated to suit all winds; but some account should be taken of the fact that, in and off the Hooghly River at least, whether the cyclone is passing up to the eastward towards Chittagong, coming straight on towards the Hooghly, or passing across the Bay to the westward towards False Point, or Balasore, the first wind blows invariably from north-east until the hard part of the storm is close upon you. No special reason has yet been advanced as to why this should be the case; yet so it undoubtedly is, as was noticed first by the late Mr. Wilson concerning a cyclone some years back, and as the meteorological registers and logs of ships during later storms well show, and which, years ago, I drew attention to in my little book, "The Sailor's East Indian Sky Interpreter."

Some authorities of the present day advise, when caught in a cyclone, that vessels should run with the wind more or less on the starboard quarter in the northern hemisphere; but, taking into consideration the now generally acknowledged wind's incurvature, and the great inset of the sea which I have drawn attention to above, there is no safety but with the wind on the starboard beam; always provided, of course, that circumstances of smooth water and sea-room allow of it. As a decisive proof of the advisability of this plan, I may mention that I was in pilotage charge of an inward-bound sailing-ship on the immediate advent of, and during, the Midnapur cyclone of June–July 1872, in which my brother, also a pilot, lost his life, on the foundering of his storm-battered ship, the *Rothsey*, in Balasore Bay. Starting from the Pilot's Ridge on the morning of June 27, under close-reefed topsails and with squared-in yards, we stood away on a south-south-east course, with a hard west-south-west gale blowing (wind on starboard beam), for thirty-six hours, and by so doing raising the rapidly-falling barometer from 29·30 to 29·50 inches, and, as I expected, getting into more moderate weather.

"Look to leeward for the weather," is the old Dutch sailor's advice, and doubtless there is a power of wisdom in the old saw, which seems to chime in better with the modern theory of eleven to twelve points rather than with the old eight-point theory. And, whilst thanking Mr. Blanford for his latest valuable contribution on marine meteorology, as set forth in his letter above alluded to, and looking forward to his promised forthcoming work on the weather and climates of India, I would point out that his directions about finding the bearings of the centre of cyclones of the Bay of Bengal seem to be just a little perplexing to some who read them, when he speaks, as he does, of the wind being three and four points before the beam, while referring to a human being standing with his back to the wind, &c. Of course, what is meant is, supposing a vessel has her stern to the wind, or running with the wind right aft, the centre will be three and four points before the "port" beam; or, in other words, if the wind is, say, north-east by north, the centre of the storm will bear south-south-east or south by east, and not south-east by east, or south-east, as it appears is still stubbornly taught by those who should know better.

A vessel in the northern hemisphere on the starboard tack, unless she happens to be sailing on the same course as the storm, and slower than it is travelling, is invariably going out of bad weather into finer, and out of bad into worse weather when on the port tack.

But much has to be said with regard to this rule of keeping the wind on the starboard beam, with a view of hastening the vessel's distance from the centre and from the hurricane belt of a cyclone. In the first place, on the left-hand semicircle, each squall, as we have above noticed, bursting down from aloft, comes from the right hand of the surface wind, which it displaces, and the vessel necessarily comes up in it, provided the storm is stationary, or is not fully developed; but if it has obtained much velocity, its onward progress will counteract this effect, and the wind will remain stationary in direction, or the ship will actually "break off," and, consequently, be more and more in the "trough of the sea"—a position sometimes critical for a ship if she is deep laden, and a high cross-sea is running, as there probably will be under the circumstances. In this case the only alternative left open to the shipmaster is to so reduce

his sail that the vessel will not forereach (or lay to) on the port tack, and wait until the storm passes on.

But on the right-hand semicircle the case is very different, and the starboard-tack rule is the proper one to adopt both with regard to the wind-shifts and also to the fact of the vessel always coming more and more "head on" to the sea—an all-important consideration.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. Francis Darwin, F.R.S., of Trinity College, has been appointed Reader in Botany in succession to Dr. Vines. Mr. E. H. Douty, M.A., of King's College, has been appointed Senior Demonstrator in Anatomy; and Messrs. W. S. Melsome, Fellow of Queen's College, and Mr. R. W. Michell, of Gonville and Caius College, Junior Demonstrators of the same.

The elections to the Council of the Senate this year may be regarded as generally favourable to science; Dr. Peile, Prof. Macalister, Dr. Routh, Prof. Browne, and Mr. E. Hill, being six of the eight elected. Dr. Lea, however, was unsuccessful, this being his first candidature.

SCIENTIFIC SERIALS.

American Journal of Science, November.—On the deflection of the plumb-line and variations of gravity in the Hawaiian Islands, by E. D. Preston. The observations for gravity were carried out in 1887 on Mount Haleakala on the Island of Maui, which is rather over 10,000 feet high with one of the largest extinct craters in the world on its summit. From these researches it appears that deflections of the plumb-line are greater on insular than on continental mountains, presumably owing to the lighter surrounding sea-water; that gravity is not in defect, because it is here estimated from the true sea-level, and not from a sea-level elevated by continental attraction; that deflections are greater in the vicinity of extinct volcanoes than near active ones; and that the so-called "hidden causes," which in the Himalayas give a variation of gravity several times as great as those arising from the attraction of the mountains themselves, do not exist in the Hawaiian Islands.—Mineralogical notes, by S. L. Penfield and E. S. Sperry. Beryl and phenacite are here studied for the purpose of determining the presence of alkalies in these crystalline bodies. Analytical studies are also given of several other rare minerals, such as a specimen of monazite and oligoclase from North Carolina, sussexite from New Jersey, barium feldspar from Pennsylvania.—The absorption spectra of certain blue solutions, Part 2, by F. B. Pitcher. Here it is shown that blues and violets obtained by absorption in pigments and solutions, differ in several respects from those colours which approximate in hue to the longer wave-lengths of the spectrum. As a rule they are much less completely saturated, and they show irregularities of composition rarely met with in absorption reds and yellows.—An instrument for demonstrating the laws of transverse vibrations of cords and wires, by George S. Moler. The apparatus here described was designed to meet a want, felt in the laboratory, for an improvement over Melde's method of producing transverse vibrations of cords and wires.—Rhætic plants from Honduras, by J. S. Newbury. These fossils, chiefly from the San Juancito district, are clearly Upper Triassic, and greatly resemble those of the coal-bearing strata on the Yaki River, Sonora.—Energy and vision, by S. P. Langley. In this investigation the author has had mainly in view the assumption of H. F. Weber and others that the luminosity of a colour is proportionate to the energy that produces it, an assumption which is shown to be absolutely groundless.—Mr. J. H. Long has a paper on circular polarization of certain tartrate solutions, and Mr. W. E. Hidden sends some notes on some specimens of xenotime from New York and North Carolina.

Bulletins de la Société d'Anthropologie, tome xi. Série 3 fasc. 1 (Paris, 1888).—On aphasia, by M. Hervé, who draws attention to a case recorded by Larrey sixty years ago, of a soldier, wounded at Waterloo on the left frontal, who lost his memory of words, more especially nouns. After death the ball was found close to the dura mater, but separated from it by the portion of bone embedded with it at the moment of the accident. The case is curious as having been recorded so long before Broca's discovery of the localization of speech.—Monstrosity of the left upper extremity, by M. Variot. The relatively small but otherwise normally formed left hand appears to proceed directly from the stump of the flattened shoulder with no trace of arm, or forearm. The body presents no other anomaly.—The history of the various modifications effected in the ship's rudder, by M. O. Beauregard.—On certain customs, connected with phallic worship, common to the Abyssinians and the ancient Spartans.—On cannibalism and its assumed origin. The consideration of these questions at an earlier meeting by M. de Nadaillac has been again made the subject of an animated discussion between himself and M. Mortillet; for, while the latter believes that this practice must originally have emanated from some perverted religious idea, M. de Nadaillac refers it solely to the promptings of famine, which is capable of engendering in man, if not mania, a depraved taste, and bestial inclinations, which civilization has never been able wholly to eradicate. The absence of animals adapted for human food he considers to have been a powerful factor in widely remote lands, as Mexico, Tierra del Fuego, New Zealand, the Pacific Islands, &c., where the people under various stages of civilization and barbarism have alike practised cannibalism, whether as a national rite or a social custom. The discussion supplies an exhaustive treatise on the subject, which at a subsequent meeting of the Society was again considered at great length by Dr. Bordier, who concludes his comprehensive essay by showing that, as the dental system in man, as in the other Primates, does not allow us to assume that in his primitive condition he was carnivorous, we must consider cannibalism as an acquired and not an original custom.—Communication, by M. D'Acy, regarding Palæolithic mortuary deposits in rock-caves. This paper gave rise to a discussion as to the age of human remains found at Solutré, Furfooz, Spy, Mentone, &c., M. de Mortillet regarding them in opposition to M. D'Acy as Neolithic, rather than Palæolithic.—On the choice of a fixed point of departure for cranial measurements, by Dr. Fauvelle. This the writer considers is to be sought at the base of the cranium, at the cerebral extremity of the vertebral column, where alone one definite point can be found which is always the same in the entire series of the Vertebrata, being indicated in the embryo by the anterior terminus of the dorsal cord, and in the adult by the posterior portion of the first cervical nerve.—The present number of the *Bulletins* contains the ordinary annual report of the statutes, rules, &c., of the Society.

Fasc. 2.—Continuation of the discussion on cannibalism reported in the previous number, and treating specially of the character and adaptability of the dental system in man.—On woman in relation to cannibalism in Polynesia, by M. Letourneau. The exclusion of women from cannibal feasts in some members of this group is referred to a greedy desire on the part of the chiefs to reserve such enjoyments for themselves. Human flesh being early tabooed to women, they gradually acquired a strong distaste for it, which in course of time was transmitted as an hereditary characteristic even to their male descendants, some of whom, as the majority of the Tahitians, had begun to manifest a repugnance for this species of food as early as the time the islands were first visited by Captain Cook.—On the ethnology of Le Rouergne, by M. Durand de Gros. The author regards this district as chiefly Iberian in character, and considered that the whole of the Department of Aveyron, with L'Hérault and La Lozère, forms the eastern confines of a remarkable linguistic region, comprising the whole of ancient Aquitania. He points out that the Garonne is a phonetic frontier, to the north of which all forms of local *patois* possess the letter *f*, while on the opposite side that character is replaced by *h*, the *filha*, *ferre* (*fille*, *fer*), of the peasants on the right bank, being pronounced *hilha*, *herre*, by those on the left. The paper supplies much interesting matter in regard to the various linguistic currents that have been successively incorporated in the main stream of the vernacular through consecutive immigrations; Latin, Celtic and Teutonic suffixes being often associated with some alien root in the names of families and places. The brachycephalic character of the district is at present very strongly marked, while the crania belonging to ancient times, as those found in the dolmens of La Lozère, are without exception dolichocephalic.—On the stature of the Parisians, by M. Manouvrier. A comparative analysis of the results yielded for the twenty arrondissements of Paris shows that, other conditions being equal, affluence, and the absence of want and of the necessity for excessive labour, have a favourable influence on the stature

of a man. It is found, moreover, that while the mean height of Frenchmen belonging to families in easy circumstances does not notably alter, it is being very sensibly diminished among the poor.—On the skull of an adult gorilla, by M. Hervé.—On prehistoric discoveries in Portugal, by M. de Mortillet, who reports the recent inauguration at Lisbon of a course of lectures on archæology by M. da Silva, to whom we are indebted for the discovery of a deposit near Leiria, in which flat hatchets and other instruments have been found, all of which are of pure copper.—The Neolithic Age at Champigny, on the Seine, by M. E. Rivière. The finds at this station have been rich in flint and other stone instruments, with fragments of coarse pottery, but they contain few bone remains, these belonging moreover, with the exception of the elk, to ordinary domestic animals. No human bones have been obtained.—On certain anthropological researches in the Caucasus, by M. E. Chantre. This communication supplies an interesting summary of the author's important work on the anthropology of the Caucasian district, which is based on the result of personal observations, and a careful study of the human and other remains derived from numerous ancient tribal burial-places, and is copiously provided with tables of comparative cephalic and other anthropometric determinations.—On a prehistoric station at Aragua, Venezuela, by M. Marcano.—A prehistoric necropolis at Saint Ellier (Maine-et-Loire) by M. Bonnemère.—On the mammillated menhirs of Sardinia, by M. de Mortillet.—On aphasia, by M. Ploix. This paper, which is mainly based on the deductions of Broca, gave rise to repeated discussions, in which Dr. Fauvelle and others took an active part in defending their special views as to the localization of speech.—Communication, by M. Hervé, on his memoir entitled "Broca's Convolution in the Primates." The writer demonstrates the claims of Leuret to be regarded as the first who recognized in the brain of the Simiadæ the prototype of the convolutions of the human brain, his discovery of a cerebral type common to all the representatives of the group of Primates having preceded by thirty years the researches of Darwin, Huxley, Vogt, and Broca.—On the efficacy of the poisons used in olden times in Europe, and still employed by Negritos and others, for tipping arrows and other weapons, by M. Laborde.—On a case of congenital blindness and deafness, with mutism, reported in New York, and communicated by M. de Nadaillac.—On cannibalism in Madagascar, as recorded in the work of M. de Flacourt in 1650, by M. Beauregard.

SOCIETIES AND ACADEMIES.

London.

Linnean Society, November 1.—Mr. W. Carruthers, F.R.S., President, in the chair.—Prof. Bower exhibited and made remarks upon some adventitious buds on a leaf of *Gnetium gnemon*.—Mr. John Young exhibited (1) a rare bird (*Pluvianellus sociabilis*), unobserved for fifty years, and lately rediscovered by him in Patagonia; (2) a cluster of nests formed of lichen (*Usnea*) by a swift, as supposed of the genus *Collocalia*, from a cave in Eimeo, one of the Society Islands; (3) remarkably elongated tail feathers of domestic cock (11 feet in length), artificially produced by the Japanese; (4) nest and eggs of the snow bunting (*P. nivalis*), taken during the past summer in Scotland.—Mr. Thomas Christy exhibited a new method of transmitting light to a microscope by means of a curved rod of glass.—The Rev. R. Baron read a paper on the flora of Madagascar, in which he gave an interesting account of his explorations and collections in that country.—In another paper, entitled "Further Contributions to the Flora of Madagascar," Mr. J. G. Baker, F.R.S., described the principal novelties brought home by Mr. Baron, and paid a well-deserved tribute to his energy and ability as a botanical explorer.

Mathematical Society, November 8.—Sir James Cockle, F.R.S., President, in the chair.—At the commencement of the meeting the Chairman feelingly dwelt upon the loss the Council and the Society had sustained by the recent decease of Arthur Buchheim (see NATURE, vol. xxxviii. p. 515).—The gentlemen whose names were given in a recent issue having been elected on the new Council, the new President (J. J. Walker, F.R.S.) took the chair, and called upon the retiring President to read his address on the confluences and bifurcations of certain theories.—Other communications that were made were:—Cyclotomic functions, § 1, groups of totitives of n; § 2, periods of nth roots of unity, by Prof. Lloyd Tanner.—On a theory of rational symmetric functions, by Captain P. A. MacMahon, R.A.—The factors and summation of $1^r+2^r+\ldots+n^r$, by Rev. J. J. Milne.—Raabe's Bernoullians, by J. D. H. Dickson.—Certain algebraical results deduced from the geometry of the quadrangle and tetrahedron, by Dr. Wolstenholme.—On a certain atomic hypothesis, by Prof. K. Pearson.—On deep-water waves resulting from a limited original disturbance, by Prof. W. Burnside.

Entomological Society, November 7.—Dr. D. Sharp, President, in the chair.—M. A. Wailly exhibited a large and interesting collection of Butterflies recently received from the Gold Coast and other parts of West Africa. The collection included about forty-seven species belonging to the genera *Papilio*, *Diadema*, *Salamis*, *Romalæosoma*, *Charaxes*, *Harma*, *Eurypheme*, *Junonia*, *Aterica*, *Hypanis*, *Eurytela*, *Mycalesis*, *Cyrestis*, *Nepheronia*, *Mylothris*, *Belenois*, &c. M. Wailly stated that several of the species were undescribed, and were not represented in the British Museum collections.—Mr. Jenner-Weir exhibited four bred specimens of Ant-lions, two of which were from Saxon Switzerland, and the other two from Fontainebleau. He stated that he believed the specimens belonged to two distinct species. Mr. McLachlan said that the specimens all belonged to one species, viz. *Myrmeleon formicarius*, Auct. = *europæus*, McLach.—Mr. W. C. Boyd exhibited an example of *Pterophorus zetterstedtii*, taken at Sydenham. He remarked that this species had hitherto only been recorded from Lynmouth and Folkestone.—Mr. Enock exhibited specimens of *Cecidomyia destructor* (Hessian Fly), illustrating the life-history of the species, and made remarks on them.—Mr. Wallis Kew exhibited a specimen of *Dytiscus marginalis* having a small bivalve shell attached to one of its legs. The bivalve had apparently attacked the *Dytiscus* and refused to relax its grasp. A discussion ensued, in which Dr. Sharp, Mr. Stainton, and Mr. Kew took part.—Mr. W. E. Nicholson exhibited several specimes of *Acidalia immorata*, Linn., caught by him near Lewes. Mr. Jenner-Weir observed that the species had only recently been added to the British list, and that it was remarkable how so comparatively large a species could have been hitherto overlooked. It was also remarked that a specimen of this species from the collection of the late Mr. Desvignes had been exhibited by Mr. Stevens at the meeting of the Society in November 1887.—Dr. Sharp exhibited a large number of species of Rhynchophora, collected by Mr. George Lewis in Japan.—Mr. F. P. Pascoe read a paper entitled "Descriptions of New Longicorn Coleoptera."—Dr. Sharp read a paper entitled "The Rhynchophorous Coleoptera of Japan."

Paris.

Academy of Sciences, November 3.—M. Janssen in the chair.—Essay on the theory of the Belleville carriage-spring, by M. H. Resal. This spring, devised about twenty-five years ago, has yielded excellent results in its application to railway rolling-stock. Here the principle of its action is worked out theoretically.—On the advantages of the use of electric light in the observations of marine zoology, by M. de Lacaze-Duthiers. An account is given of the system of electric light now in use at the Arago Laboratory of the Banyuls station, by means of which the author has been enabled to carry out some of his most important recent observations on marine life. The transparent animals especially can be studied with great advantage in a luminous atmosphere, revealing even the embryonic organisms, which cannot be detected in ordinary light.—Positions of Barnard's comet (September 2, 1888) measured at the Observatory of Besançon, by M. Gruey. The observations were taken jointly with M. Hérique for the period from October 11–17.—Observations of Barnard's new comet (October 30), and of Palisa's new planet, 281, made at the Paris Observatory (equatorial of the west tower), by M. G. Bigourdan. The positions of the comparison stars and the apparent positions of the comet and of the planet for November 3 are given.—On a triple determination of the latitude of the Gambey circle, by M. Périgaud. These determinations, effected by means of the new mercury bath described in the *Comptes rendus* for March 16, 1888, show that the latitude of the circle is as nearly as possible 48° 50′ 10″·9. It also appears that the latitude does not vary with the seasons, the result obtained in October 1888 being identical with that previously determined by the same instrument in June 1887.—On a means of studying the slight deformations of liquid sur-

faces, by M. J. B. Baille. Fizeau's extremely delicate method of measuring minute distances is susceptible of a large number of applications, and is here employed accurately to determine all the deformations of a liquid surface, however slight be the actions causing them. By this process the author has been enabled to observe the surface deformation of magnetic and diamagnetic fluids under the action of a weak magnet. He also shows that, as a copper wire traversed by a strong current attracts iron, it also attracts the surface of the perchloride of iron in solution.—On the occlusion of gases in the electrolysis of the sulphate of copper, by M. A. Soret. The author's researches lead to the conclusion that the electrolyzed copper always contains a certain quantity of gas, almost exclusively hydrogen. It retains a little carbonic acid and sometimes a very slight quantity of carbon oxide. A certain relation exists between the quantities of gas occluded and the conditions of temperature and acidity; consequently the quantity of gas present in the metal is variable, and the proportion 4·4 volumes, given by Lenz (*Journ. prakt. Chem.*, cviii. p. 436), is applicable only to the particular case studied by that physicist.—On tin, by M. Léo Vignon. If a zinc plate be plunged into an aqueous solution of one of the tin chlorides, the latter metal is precipitated by the zinc according to certain known thermo-chemical relations. The tin so precipitated possesses some special properties, which are here studied for the first time. An inquiry is also made into the cause of this modification of the fundamental properties of tin. The result of this inquiry is that the modified tin, which is infusible, is a mixture of metallic tin and of the anhydrous protoxide of tin.—On the homopterocarpine and pterocarpine of red sandalwood, by MM. P. Cazeneuve and L. Hugounenq. These two extracts of red sandalwood, described in the *Comptes rendus*, civ. p. 1722, are here methodically studied under the action of the chief reagents. Their respective formulæ are now shown to be $C_{24}H_{24}O_6$ and $C_{20}H_{16}O_6$, and there can be no longer any doubt that pterocarpine is a lower homologue of homopterocarpine.—On a substance at once acid and basic contained in cod-liver oils, by MM. Arm. Gautier and L. Mourgues. This substance, to which the authors give the name of morrhuic acid presents considerable interest owing to its double function of an acid and an alkali, as well as for its relative abundance and its origin, which is probably connected with the vegetable lecithines. It is present in these oils under the form of an unstable and complex combination, behaving like the ordinary lecithines—that is, it is modified, especially when heated in the presence of acids and alkalies, liberating glycerine, phosphoric acid, and a complex acid. It corresponds to the formula $C_9H_{13}NO_3$.—M. V. Marcano describes a fermented drink (*yaraque*) extracted by the wild tribes of the Upper Orinoco from Cassava; M. Martinaud studies the analysis of the yeast of beer; and M. Émile Rivière reports on the human and animal remains found in the Caves of Baumias de Bails and Saint-Martin in the Alpes Maritimes.

BERLIN.

Physiological Society, October 26.—Prof. du Bois-Reymond, President, in the chair.—Prof. Wolff spoke on the growth of the lower jaw. Notwithstanding the opposition of some observers, Flourens's view of the growth of bone by apposition and absorption is still widely applied to the lower jaw, and Humphry's experiments on the growth of the ascending branch of the same have been advanced in support of this theory. The speaker had therefore made a large number of experiments on goats and rabbits, by firmly attaching two wire rings to the bone while the animals were still young; one ring was placed at the *pars incisiva*, the other at the angle of the lower jaw. His conclusions are based upon the results of forty-two experiments; of these twenty-three showed an increase of 7 to 9 mm. in the distance between the wire rings in three to six months, while in twelve other cases a distinct but smaller increase in the distance between them was observed, so that only seven cases yielded no positive result. Bearing in mind the value which must always be attached to a few positive results even when opposed by many negative, it appears that the above-mentioned large preponderance of cases in which an increase in the distance between the marks was observed fully justifies the conclusion that the lower jaw grows by expansion. This proof of the interstitial growth of bone, together with the proved adaptability of all bones to the statical conditions of the demands made upon them, will, Prof. Wolff hopes, put an end to the idea that bone-tissue is inactive, and replace it by the theory he has so long held that bone is capable of active vital growth even in old persons.—Dr. Hans Virchow gave an account of the results of his experiments on the development of blood and the blood-vessels in the chick. In especial he pointed out that the blood is developed very early in the mesoblast, and takes up a peculiar position in the same. He next spoke on the yolk-sac of the chick. After he had explained the chief points and results of his researches, he was obliged to defer the rest of his communication to the next meeting, owing to the lateness of the hour.

AMSTERDAM.

Royal Academy of Sciences, October 27.—M. Behrens discussed the origin of the volcanic lakes in the Eifel Mountains, and demonstrated that they could not have originated in the crumbling down of extinct volcanoes. He endeavoured to show that the Eifel Lakes must be regarded as incomplete volcanoes, and that they were formed by the softening and continuous blasting of the sedimentary rocks, only a little lava having been brought to the surface.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

The Butterflies of the Eastern United States and Canada, with special reference to New England, Part 1: S. H. Scudder (Cambridge, Mass.).—Index Catalogue of the Library of the Surgeon-General's Office, United States Army, vol. ix. (Washington).—The Invisible Powers of Nature: E. M. Caillard (Murray).—Thermodynamique: J. Bertrand (Paris, Gauthier-Villars).—Untersuchungen über Dammerungserscheinungen: J. Kiessling (Hamburg, Voss).—University College, Nottingham, Calendar 1888–89 (Nottingham, Sands).—An Introduction to Entomology, Part 1: J. H. Comstock (Ithaca).—Annual Report of the Secretary for Mines and Water Supply, Victoria (Melbourne, Brain).—Foreign Aviary Birds, &c.: Dr. K. Russ (Dean).—Macaws, Cockatoos, Parrakeets, and Parrots: Sir T. D. Lauder and Captain T. Brown (Dean).—Euclid's Elements of Geometry, Books I.–IV.: A. E. Layng (Blackie).—Questions and Examples on Elementary Experimental Physics: B. Lœwy (Macmillan).—Practical Metallurgy and Assaying: A. H. Hiorns (Macmillan).—Gleanings in Science: G. Molloy (Macmillan).—Sitzungsbericht der K. CONTENTS.

THURSDAY, NOVEMBER 22, 1888.

THE OPENING OF THE PASTEUR INSTITUTE.

"WE cannot refrain from expressing some regret that the encouragement of scientific research should be one of the things which they do better in France than among ourselves." With these words, trenchant enough if heeded by those in authority on whose ears they may fall, the *Times* concludes a leader on the inauguration of the Pasteur Institute by the President of the French Republic. Such a ceremony naturally suggests two distinct points for consideration: (1) the object of the institution thus inaugurated; (2) the interest attaching to the ceremony.

The Pasteur Institute is remarkable among all others in being the best form of monument ever erected, and at the same time in its being raised during the life-time of the distinguished man of science, in whose honour and for the furtherance of whose work it was designed. That the debt which the community owes to M. Pasteur will never be paid, nor even adequately acknowledged, needs no insistance; but we may be excused if we dwell upon this point a little, for in the multifarious and different battalions of the workers in the army of science there may well be some whose particular work has not quite brought home to them their obligation to him.

The most remarkable characteristic of M. Pasteur's work, the one which places it on so unique a pedestal, is the fertility of its results in every direction. To have elucidated at once the causation of most forms of fermentation, and the causation of most forms of acute febrile disease (this last leading to the infinitely precious invention by Sir Joseph Lister of antiseptic surgery), is on the chemico-biological side of natural science a feat of as great abstract value and of greater immediately practical worth to the community than any one, or even two, of the greatest epoch-making discoveries of physical science. If it were not for the lamentable consequences of the apathy with which the British public regard science and its contributions to their health and wealth, it would be sadly amusing to read, as anyone may do in even well-founded prints, the lay opinion that M. Pasteur is but a hydrophobia curer, and possibly a slightly more successful one than McGovern, the Irish quack. The flame of popular knowledge of current science always burns most unsteadily, and any sensational wind makes it flare for a short time, and then it sinks almost extinguished. It has thus been with the most recent work of M. Pasteur; and so we find at the inauguration of the Institute the wide subject of the chemico-biology of disease processes was subordinated to the representation of the existing condition of our knowledge of the treatment of rabies.

Although, considering the national importance of the general principles of M. Pasteur's work, this preponderance of attention given to one subject may be regretted, it nevertheless must be admitted that a specific instance is more easily "understanded of the people," and may consequently more energetically drive home the wedges of scientific truth. To M. Grancher was most justly accorded the very agreeable task of expounding in a few simple and unadorned sentences the results of the anti-rabietic treatment of M. Pasteur. Though rabies, or hydrophobia, has always occupied such a special position in the public mind, this has not prevented the application of the general principle of public ingratitude; and we are therefore in no wise surprised to find that the benefactor who arose, and, at his own risk and cost, attempted to remove such an evil, should have been received with calumny and misrepresentation. The consolation afforded by the unerring verdict of time rarely comes—as in the present case it fortunately has to M. Pasteur—before the benefit-conferring Prometheus is past receiving it.

M. Pasteur has always borne the monstrous attacks made upon him with such dignity and composure, that the summary by M. Grancher of the great works suggested by him must have been an intense gratification and recompense.

Our sympathy with his pleasure is unfortunately alloyed with regret that of recent years health has been denied him for the perfect enjoyment of his renown.

The announcement by M. Pasteur in 1885 (the year of the epidemic of rabies in London) that he had not only succeeded in rendering dogs refractory to rabies by means of prophylactic inoculations, but had also with the same material attempted, and apparently successfully, the curative treatment of two human beings, marked the commencement of a widespread application of his now fairly well-known methods.

From the first, M. Pasteur recognized the effect that such an announcement would have upon the public mind, and, in addition to forming a resolution only to treat assured cases of rabies (a resolution he had ultimately to abandon on the grounds of humanity), arranged the facts of his work in such a manner as to provide for complete statistical accuracy in his records.

By his prescience we are thus placed in possession of an overwhelming series of facts relating to persons bitten by rabid animals. He arranged those who came to him under these circumstances into three categories.

In the first (Class A) he placed persons bitten by animals indubitably proved to be rabid by the results of inoculation from the spinal cord into normal animals.

Secondly (Class B.), he grouped together those cases in which the state of the animal, though not tested by experiment, was nevertheless certified to have been rabies by a veterinary surgeon.

Finally, he constructed a third order (Class C.) in which were collected those cases in which, owing to escape, &c., of the dog or animal attacking, no precise information as to its condition could be obtained, but only a presumptive suspicion that it was rabid.

Before we review the figures derived from these three classes of patients, it is important to gauge the character of the statistics of the general mortality from the disease with which they have to be compared. It is only since special attention has been drawn to rabies through M. Pasteur's work that trustworthy statistics have been forthcoming. In former years estimates of various kinds were from time to time prepared, but while some authors took only cases of the most virulent kind, and consequently obtained exceedingly high death-rates among those bitten, others accumulated large numbers of instances the details of which were most imperfectly

ascertained, and the mortality percentages thus deduced consequently utterly untrustworthy. The severest test that could be conceived for genuine criticism of M. Pasteur's method is obviously the comparison of the death-rate in his Class A. with that among persons, not his patients, proved to have been bitten by rabid dogs by the fact of at least one of those attacked by the animal dying of the disease. Such a comparison is now fortunately possible. The probability of rabies following the bite of a rabid dog is now definitely ascertained to be from 15 to 16 per cent. of those attacked.

Now the death-rate in M. Pasteur's Class C. is no more than 1·36 per cent., even including every fatal case—that is, inclusive of those persons who develop the disease during the first fifteen days after the bite. The rigid comparison of these two death-rates may well afford M. Pasteur the satisfaction of feeling that he has saved a number (to be counted by hundreds rather than tens) of his fellow-creatures from the most agonizing of deaths, and an enormous number from the worst of apprehensions.

For general biological science the next most interesting statistics are those which seem to reveal the mode of action of the curative and prophylactic inoculations. M. Pasteur's explanations of the beneficial effects of the material inoculated was that the nerve-tissue contained not only the microbes, the causative factors of the disease, but also their metabolic products, and that these latter by accumulation inhibit the growth and spread of the organisms. If, therefore, these products were injected into the blood-stream in sufficient quantity, he believed that the animal so treated would be protected from the malady. In this country Dr. Wooldridge had already proved experimentally the occurrence of such a process in the case of anthrax or splenic fever. Now the accumulated experience of M. Pasteur's laboratory goes very far to establish this theory for rabies also. Thus in Russia, where rabies is frightfully prevalent by reason of its being endemic among wild (wolves notably) as well as among domestic animals, the figures obtained from the respective inoculation stations are most striking :—

	Odessa death-rate per cent.	Moscow death-rate per cent.	Warsaw death-rate per cent.
1886. "Traitement simple" (*i.e.* small quantities injected)	3·39	8·40	3
1888. "Traitement intensif" (*i.e.* large quantities injected)	0·64	1·60	0[1]

It is abundantly evident from these figures that successful protection is due to the energy and frequency with which inoculations are practised, or, in other words, to the quantity of protective material injected. While we cannot too heartily congratulate M. Pasteur on his triumph in finding a cure for this miserable disease, we feel very glad that, since his work has established the true nature of rabies and its mode of propagation among animals and men, the French authorities have at last awakened to the fact that there is no disease which can be more successfully prevented by legislation. M. Grancher exhibited a chart showing the immediate effect of preventive legislation in reducing the prevalence of the malady in the Department of the Seine. For us, our own experience of the measures whereby the disease was temporarily extirpated from London (though now, of course, reappearing since the relaxation of the restrictions) is so strong that we hope this additional evidence will induce our Privy Council to apply such measures throughout the country; and having thus stamped out the disease in England, prevent by suitable contra-importation measures the re-introduction of the disease.

[1] "Intensif" treatment for last sixteen months—no death.

So much for the work of the Institute as immediately in operation. The special interest of the inauguration ceremony is noteworthy. We have already referred to it as being in part due to the personal monument it establishes to the genius of M. Pasteur, but it has a more particular interest for British national science. It lies in the fact that here we see an institution erected for the national purpose of scientific investigation into the causes of diseases and their mode of prevention. We see, moreover, the head of the Executive Government, in company with the members of his Cabinet, personally giving to the movement his cordial interest and support. It must make us all wonder when our Government will cease to regard the social and political importance of scientific investigations with other than an absolutely ineffective interest.

At present, for scientific investigations of this kind this country and its Government are positively dependent upon the charity of a private laboratory, that of the Brown Institution, the income of which, utterly inadequate, is very imperfectly helped by the defrayal on the part of the Government of simply the immediate expenses of the work done for them. And at the same time we wonder when our Government will remove the disgraceful legislative hindrances to British scientific work. Finally, we may ask, When shall we see the scientific millennium of an English Ministry taking an immediately personal interest in the welfare and support of such an institution? We can only conclude in the spirit of the words of the *Times* with which this article begins; and hope that, if it is generally appreciated how the lead has been taken from this country by France, at least an effort will be made by those who are responsible for the discredit thus forced on us to remove the blot by organizing a somewhat similar institution in England.

PRACTICAL BOTANY.

A Course of Practical Instruction in Botany. By Prof. F. O. Bower, D.Sc., F.L.S. Part I. Second Edition. (London: Macmillan and Co., 1888.)

THE first edition of Part I. of Profs. Bower and Vines's "Practical Botany" was published in 1885 (see NATURE, vol. xxxii. p. 73); and during the three years that have elapsed the book has become familiar in all botanical laboratories, and has proved an important aid to the work of both teachers and students. This first part deals with the Phanerogams and Pteridophytes. Part II., completing the work, appeared only last year (see NATURE, vol. xxxvii. p. 28), and thus the former part has reached a second edition while its companion volume is

still a new book. In preparing the new edition, Prof. Bower has no longer had the active co-operation of Dr. Vines; though, as explained in the preface, the chapters originally contributed by the latter have been almost entirely embodied in the present work. A short account of the book as it now stands may be of service to the readers of NATURE, for as compared with the former edition it has undergone considerable rearrangement and extension. In both these respects the first three chapters, which are introductory to the study of the types, show important changes. The book begins with a list of apparatus, and of the more ordinary reagents, the mode of preparation of which is described. A more detailed list of reagents is now given in the first of the new appendices at the end of the volume.

Chapter I. deals with the making of preparations, and the adjustment of the microscope. Under both heads the directions are most practical and excellent, and cannot be too strongly commended to the attention of students. This chapter is essentially elementary; and only simple methods, such as are indispensable for all workers, are included. A very clear account of section-cutting is given, and in Fig. 1 a diagram is added in order to explain the meaning of "radial" and "tangential" sections, a point which is often puzzling to beginners. The introduction of diagrams is an important feature of the new edition. Though not very numerous (fifteen in all) they will be found a very useful help. Strictly diagrammatic figures have been used in all cases, in order that the student may not be tempted to make use of the illustrations as substitutes for the objects illustrated. The first chapter concludes with instructions on drawing from the microscope, and on measurement.

Chapter II. contains a number of "practical exercises." In the first of these the microscopic examination of the pulp of an apple serves to make the student acquainted with the general characteristics of vegetable cells.[1] The next exercise is on Spirogyra, and the third on the Fern-prothallus. A reference to the general account of the prothallus at p. 300 would here be useful to the beginner. Next comes the Beet-root, the first object of which sections have to be made. Here the chief osmotic phenomena are studied. Protoplasmic movements are illustrated by Trianea or Hydrocharis, and by Tradescantia. The last exercise (in small print) is on cell-division, as shown in the staminal hairs of Tradescantia. This, we think, would have been better omitted at this place. It is impossible in a few lines to give a satisfactory account of so complicated a process, and inaccuracies can scarcely be avoided. Thus the statement that the nuclear "fibres are ruptured in the equatorial plane" cannot be accepted in the light of our present knowledge.

The third chapter, headed "Micro-chemical Reactions," gives a series of further practical exercises of a more advanced character. These are only in part designed for the beginner, and those which he is intended to work through are indicated by a marginal line. The remaining parts of the chapter are designed to be used for purposes of reference, during the subsequent investigation of the types. The improved account of the chlorophyll-grains (p. 51) and the fuller description of vegetable oils (p. 59) may be especially noticed. Into this chapter an adequate account of the chief facts relating to the division of the cell and nucleus might perhaps have been introduced with advantage, as their satisfactory observation with the help of modern methods is by no means beyond the powers of the more advanced students.

The introductory portion of the work terminates with some useful remarks on staining, clearing, and permanent mounting (pp. 65–70).

The study of the Dicotyledonous types begins with an examination of the seed and embryo in the Bean, the Cucumber, the Sunflower, the Castor-oil plant, and the Marvel of Peru. In the reviewer's opinion it would have been better to begin at once with the seedling, as the structure of the seed cannot possibly be really understood until the reproductive organs have been investigated. This especially applies to the last example cited, namely, Mirabilis, the description of which will, we fear, be found very puzzling by the student.

The main outlines of the description of types remain as in the former edition. Only a few of the chief alterations need be mentioned. Two excellent diagrams of bundle-systems (after Reinke) are introduced at pp. 79 and 81, while the investigation of the seedling Sunflower by means of successive transverse sections is a most valuable addition to the treatment of the difficult subject of the distribution of vascular bundles. Attention may be called to the remark, on p. 96, that the work on the *young* stem of the Sunflower may with advantage be taken earlier. The structure of the stem before secondary thickening has begun must certainly be understood in order that the subsequent changes may be intelligently studied. Diagrams, after Sachs, are introduced at p. 98 to illustrate the origin of the cambium, and at pp. 100 and 102 to show the arrangement of the cells at the apex of the stem. In the account of the periderm (p. 107) the terminology has been revised, and now agrees with that of De Bary. This subject is now illustrated by diagrams. These are original, and so also are those on p. 122, by which the form of cambial cells is explained.

At p. 137, the intercellular space beneath the stoma is still called the "respiratory cavity." This term, though so generally used, is likely to mislead beginners as to the function of the stomata, and the colourless phrase, "air-chamber," seems preferable. To the account of the structure of the petiole, a description of the pulvinus in the French Bean is now added. The Holly has been substituted for the Cherry-Laurel as the type of a coriaceous bifacial leaf; while, as examples of "iso-bilateral" structure, the phyllodes of Acacia, and the leaves of *Eucalyptus globulus*, are introduced. The aquatic type of leaf is well illustrated by Hippuris, in which the sub-aërial and the submerged leaves are compared. Passing by several minor additions, the valuable new section on the fall of the leaf may be especially noted. An account of hairs and emergences has also been added, in small type.

The work on the root of Dicotyledons has been expanded, and the very clear original diagram of its transverse section, before and after secondary thickening, is likely to be of great service.

The stem of the Monocotyledons is now described in two additional types—the Hyacinth, as a bulbous plant, and Elodea, as an aquatic. The last-named plant is also

[1] A misprint on p. 27 (line 4) may be noticed, where the word "as" has been omitted.

used to illustrate the modifications shown by submerged leaves, while the leaf of Iris is introduced as the example, among Monocotyledons, of iso-bilateral construction. In the account of the *root* of Monocotyledons we regret that no mention is made of the exodermis or hypodermal layer. The great importance of this layer as a protective dermal structure to the older roots, especially in plants destitute of periderm, has been sufficiently shown by Olivier and others, and there seems no reason why it should any longer be ignored in elementary teaching. The exodermis is indeed mentioned (under the older, but now somewhat confusing, name of endodermis) in the new section on *aërial* roots (p. 195), but it would be a mistake to suppose that it is by any means confined to roots of this category.

The work on the reproductive organs of Angiosperms has been on the whole but little altered, the naked-eye observation of various typical flowers being the most important addition. In the account of the Blue-bell (p. 203) it would perhaps be well to define the *perianth*, as beginners often fail to see that it corresponds to both calyx and corolla. The Rhododendron is introduced (p. 215) for the study of pollen-tubes. The section on the development of endosperm, and on the continuity of protoplasm between its cells, is new (p. 218).

Going on to the Gymnosperms, we find that the description of the stem of Abies now precedes that of Pinus doubtless on account of the simpler external morphology of the former. In the histological examination of the wood of Pinus we are sorry that the expression "irregularities of structure called bordered pits" has been allowed to stand (p. 230), as it does scant justice to these singularly beautiful organs. The introduction of the leaf and the root of the Yew is a great gain to this part of the anatomical investigation, while the description of the reproductive organs of the same plant is of even greater value.

Among the Pteridophyta, the chapters on Selaginella and Lycopodium have scarcely been altered. It may be pointed out that it is not quite accurate to describe the phloëm in the vascular cylinder of Lycopodium as forming a matrix (p. 268), for the true phloëm is limited to the isolated bands of tissue which alternate with the groups of xylem.

In the account of the homosporous Ferns the most important change is the introduction of Pteris for the minute structure of the vascular bundle. For this purpose it is certainly the best easily accessible type. Several useful diagrams now illustrate this chapter, among which that of the vascular skeleton of the Male Fern, will be especially welcome.

Pilularia is added as a new type, representing the heterosporous Filicineæ. It is certainly well that the student should be made acquainted with this interesting group of plants, and this addition may perhaps be regarded as the most important in the book. The relation of the vascular bundle in Pilularia to that of the true Ferns might have been made somewhat clearer if that type of bundle had been described, in which the two ends, as seen in transverse section, are not completely confluent.

Three appendices and an index have been added to this edition, the index referring to both parts of the book. Appendix I. includes reagents, and the method of preparing them. Appendix II. gives the reactions of the various substances occurring in plants: and Appendix III. is a most useful list of material, with directions for obtaining it. This last appendix is in two divisions, the second of which contains the material required for Part II. (Bryophyta—Thallophyta).

The extensive changes which this volume has undergone have rendered it more than ever an invaluable aid to the study of plants in the laboratory. English students may be congratulated on their good fortune in possessing such a hand-book, and we may confidently hope that the present edition of Prof. Bower's work may render even greater services to scientific education than did its predecessor.

D. H. S.

THE SENSES, INSTINCTS, AND INTELLIGENCE OF ANIMALS.

The Senses, Instincts, and Intelligence of Animals, with Special Reference to Insects. By Sir John Lubbock, Bart., M.P., F.R.S., D.C.L., LL.D. "International Scientific Series," Vol. LXV. (London: Kegan Paul, Trench, and Co., 1888.)

MUCH consideration of the ways of ants has imparted to Sir John Lubbock so large a measure of the wisdom of industry, that even King Solomon himself could scarcely have failed to appreciate the result. The work which has just appeared under the above title may be regarded as a sister volume to the "Ants, Bees, and Wasps," in the same scientific series. Its scope, however, is wider, and, in consequence, its subject-matter is calculated to be of even more interest to the general public, notwithstanding that "Ants, Bees, and Wasps" is already in its ninth edition.

"The Senses, Instincts, and Intelligence of Animals" runs to close upon three hundred pages, of which only about the last fifty are devoted to instincts and intelligence. The book, therefore, is primarily a treatise on the organs of special sense throughout the animal kingdom. As such, it deserves to be regarded as a valuable contribution, not only to the library of the general reader, but also to that of the working biologist. For while, on the one hand, it does not presuppose even the most elementary knowledge on the part of its readers, on the other it constitutes an excellent hand-book of reference to the principal literature on the subject. Of course, in the latter respect it is by no means exhaustive, nor does it profess to be what we understand by a text-book. Nevertheless, it will prove exceedingly useful as a book to be consulted by any naturalist who, having previously worked in other lines, may have occasion to require an index to the more important literature of sense-organs, especially of the Invertebrata. Considerably over one hundred authors are alluded to, and the essay is illustrated by 118 woodcuts, derived from the original memoirs quoted.

A considerable portion of this essay is occupied with an account of the author's own experiments on the special senses of insects, &c., together with replies to criticisms which have been advanced by high authorities in Germany and France, both as against some of his facts and some of his inferences. Without going into particulars, we may

say that in every case these replies appear to us completely satisfactory, and are everywhere rendered in a manner the courtesy of which not many English naturalists could nowadays emulate. But, besides answering criticisms, he has in several cases important criticisms to make. For instance, we have a tolerably full republication of his research upon the colour-sense of Daphnia, whereby he so completely overturned the results previously published by the late M. Paul Bert. The following is a good example of the application of his criticism in another direction:—

"With reference to the power which insects possess of determining form, Plateau has recently made some ingenious experiments. Suppose a room into which the light enters by two equal and similar orifices, and suppose an insect set free at the back of the room, it will at once fly to the light, but the two openings being alike, it will go indifferently to either one or the other. That such is the case Plateau's experiments clearly show, and, moreover, prove that a comparatively small increase in the amount of light will attract the insect to one orifice in preference to the other. It occurred, then, to Plateau to utilize this by varying the form of the opening, so that, the light admitted being equal, the opening on the one side should leave a clear passage, while that on the other should be divided by bars large enough to be easily visible, and sufficiently close to prevent the insect from passing. . . . The insects seem to have gone most often to the trellised opening. M. Plateau concludes that insects do not distinguish differences of form, or can only do so very badly. I confess, however, that these experiments, ingenious as they are, do not seem to me to justify the conclusions which M. Plateau draws from them. Unless the insects had some means of measuring distance (of which we have no clear evidence), they could not tell that even the smaller orifice might not be quite large enough to afford them a free passage. The bars, moreover, would probably appear to them somewhat blurred. Again, they could not possibly tell that the bars really crossed the orifice, and if they were situated an inch or two further off they would constitute no barrier. I have tried some experiments, not yet enough to be conclusive, but which lead me to a different conclusion from that of M. Plateau. I trained wasps to come to a drop of honey placed on paper, and, when the insects had learnt their lesson, changed the form of the paper. . . . It certainly seemed to me that the insect recognized the change."

In the remaining portion of the book, or the portion which deals with "Instinct and Intelligence," we have three chapters. The first is an admirable discussion of one of the most wonderful instincts in the animal kingdom, viz. that of the Sphex stinging only the nerve-centres of the spiders, insects, or caterpillars, which she thus paralyzes without killing, before inclosing them with her progeny, whose food they are afterwards to constitute. Sir John has some good critical remarks to offer on the subject, and also some shrewd speculations upon the possible origin of the instinct. His hypothesis very much resembles that which was arrived at independently by the late Mr. Darwin, and which, therefore, is now in part quoted by Sir John. The quotation runs:—

"I suppose that the sand-wasps originally merely killed their prey by stinging them in many places, and that to sting a certain segment was found by far the most successful method, and was inherited like the tendency of a bull-dog to pin the nose of a bull, or of a ferret to bite the cerebellum. It would not be a very great step in advance to prick the ganglion of its prey only slightly, and thus to give its larvæ fresh meat instead of only dried meat."

Here, by the way, we have an excellent instance of the difficulty which we so often encounter in the domain of instinct, when we relinquish the so-called Lamarckian principle of the inheritance of acquired characters. The hypothesis in question goes upon the supposition that some of the ancestors of the Sphex were intelligent enough to notice the peculiar effects which followed upon stinging insects or caterpillars in the particular regions occupied by nerve-centres, and that, in consequence of being habitually guided by their intelligence to sting in these particular regions, their action became hereditary, *i.e.* instinctive. But if, in accordance with post-Darwinian theory, we relinquish this possible guidance by intelligence, and suppose that the whole of this wonderful instinct was built up by natural selection waiting for congenital (*i.e.* fortuitous) variations in the direction of a propensity to sting, say, the nine nerve-centres of a caterpillar—then it surely becomes inconceivable that such an instinct should ever have been developed at all.

A chapter on the supposed sense of direction among the Social Hymenoptera, and another on his now well-known experiments in teaching a dog the use of written signs, bring to a close one of the most instructive and entertaining of the works which have been produced even by Sir John Lubbock.

GEORGE J. ROMANES.

MASSAGE.

Massage and Allied Methods of Treatment. By Herbert Tibbitts, M.D. (London: J. and A. Churchill, 1888.)

It is seldom that a medical book of such inferior quality has been issued from the press, and the fact that it has found any purchasers is a striking proof how a catching title and an attractive exterior can still mislead the public. Anyone even slightly acquainted with the subject will at once perceive that the writer, whilst professing to teach massage, has not mastered the first principles of the treatment. His modest refusal to accept the office of "high priest of massage" has, indeed, complete justification.

It is not easy to adopt any method in criticizing a work devoid of all attempt at arrangement, but from the chaos of thought and diction we will select a few samples of what the writer has considered suitable food for the minds of his readers.

At the outset the author attempts to define massage, and with a dim consciousness that he has somehow failed, he plaintively declares that his definition is misty. Out of this verbal fog he never emerges, and as he pursues his erratic course it rapidly thickens around him. He has introduced illustrations and quotations from other writers, and in mercy to his readers also gives references to standard authors, who may be read with advantage. Unfortunately he at times becomes bold even to rashness, and launches out on his own account. A few samples of the inevitable result will suffice. On p. 27, whilst in the midst of giving directions for treating the lower limbs, he intercalates the following sentence: "You then massage the muscles from the waist downwards, working

upwards as before." This has no connection with what has gone before or what follows after. On the next page he says, "for the large and small intestine you massage the lower part" (of the abdomen), having evidently forgotten the position of the transverse colon, which anatomists still believe to be a part of the large intestine. Again, after giving all the less important uses of the saliva, he entirely omits its action in changing the starchy foods into sugar, an omission of which a second-year student would scarcely have been guilty. His readers are left in ignorance of the emulsifying action of the bile on fatty foods, and the pancreas is only considered worthy of mention. In fact the writer, after intimating that the functions of the body could be very well carried on without such an important gland as the spleen, with the modern physiology of which he does not acquaint his readers, leaves us under the impression that the organization of the human body would have been much better planned had Dr. Tibbitts been the designer.

The author claims for a battery he has invented certain qualities, which he declares to be unique, although they are possessed by other machines. He claims for his hospital the honour of being the only one to which a school for massage is attached, totally ignoring what is being done at other institutions. He is the forerunner of Apostoli, and modestly likens himself to Paul and Apollos, he does not say which. "Although Paul planted, Apollos watered," is his misquotation of the Scriptures. He robs Sir James Paget of the honour of a "discovery." Sir James "suggested," but Dr. Tibbitts "originated" afterwards! After claiming on very insufficient grounds to be a forerunner, a discoverer, and a prophet, he finally declares that all the authorities before him were as blind leaders of the blind. Charcot, Russell Reynolds, Hughlings Jackson, Gowers, and such small fry, are all wrong—for has he not looked into all the authorities?—and he now announces in defiance of them the tremendous fact that there is no such thing as hysteria! However, the apparent object of the book has been attained, and the great Holloway must hide his diminished head.

OUR BOOK SHELF.

Rock-forming Minerals. By Frank Rutley, F.G.S., Lecturer on Mineralogy in the Royal School of Mines. With 120 Illustrations. (London: Thomas Murby, 1888.)

THIS book appears to supply a real want among students of that now very popular subject of study, microscopic petrography. Many of the existing text-books, which are for the most part written in German and French, demand a larger acquaintance with the principles of crystallography and physical optics than many students of the subject possess. Mr. Rutley evidently possesses a considerable experience of the wants of students, and is familiar with the kind of difficulties which prove most troublesome to them. With the greatest patience he endeavours to remove these hindrances to their progress, pointing out the different senses in which the same term is sometimes employed, cautioning them against prevalent misunderstandings, and advising them as to the best method of forming just conceptions concerning the abstruse problems with which they have to deal. Very noteworthy and excellent are the numerous drawings, which, though severely diagrammatic rather than pictorial, are admirably suited for their object. The student who follows the advice of the author, and by the aid of cardboard, cork, and pins, constructs a series of models based upon these drawings, will be able to realize the essential peculiarities of the several mineral species in a way that no amount of description will enable him to do. In the general arrangement of this book, Mr. Rutley has followed the same excellent plan as Prof. Rosenbusch in the first volume of his excellent "Mikroskopische Physiographie." The first part of the book, comprising 104 pages, is devoted to general considerations, and the second part (144 pages) to a description of the crystallographic and optical peculiarities of the chief rock-forming minerals, these being grouped according to their system of crystallization. In every part of the book there is evidence of the most painstaking care and conscientious attention to accuracy of detail, and we can heartily recommend the book to those who seek for just such an amount of information on optical principles as will enable them to employ the modern refined methods of petrographical research.

A Text-book of Euclid's Elements for the Use of Schools. Parts I. and II., containing Books I.–VI. By H. S. Hall, M.A., and F. H. Stevens, M.A. (London: Macmillan, 1888.)

WE have here the completion of a work which in its first instalment (Books I. and II.) has already won a considerable amount of favourable notice from teachers. The "end" has "crowned the work" in a similar satisfactory manner; and, without entering into any "odious" comparisons with recent like editions, we consider this to be abreast of the best. Great attention has been paid to the arrangement and composition of the text, and the difficulties which delay beginners have been carefully smoothed and explained. The ordinary proofs have been adhered to as much as possible, and, in the words of the preface, "changes have been adopted only where the old text has been generally found a cause of difficulty."

Alternative proofs are given in many cases, which are less cumbrous than those in vogue already. The subject of proportion has been treated on the system advocated by De Morgan, and here great use has been made of the admirable exposition of it given in the Association's (A.I.G.T.) text-book. The principal propositions have been established in a clear manner, both from the algebraical and geometrical definitions of ratio and proportion, and the distinction between the two modes of treatment is well brought out. The whole of this part forms a good introduction to the sixth book.

The additional feature in the complete treatise is the free use in the third and subsequent books of the signs and abbreviations which are recognized by most teachers, and allowed in the University examinations.

The explanatory matter and additional sections contain all, or nearly all, that is looked for nowadays, and include articles on harmonic section, centres of similarity and similitude, pole and polar, radical axes and transversals. The exercises in the text are well graduated, and should bring out the pupil's acquaintance with, and mastery over, the propositions to which they are appended. More difficult problems are led up to by the solution of typical examples. In conclusion, we need only say the work before us contains all that is needful to a student, who, if he has this, will require no other text-book to become an expert geometer—*i.e.* in so far as outside aid can make one.

A Class-book of Elementary Chemistry. By W. W. Fisher, M.A., F.C.S. (Oxford: Clarendon Press, 1888.)

THE number of elementary books for students of chemistry has increased so greatly during the last ten years, that each new introduction gives rise to a question as to whether the author has justified his position in adding another

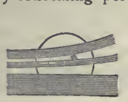
But, however far the supply exceeds the demand, there is always room for what is thoroughly good, especially if it has improvements that its predecessors lack. Though every author is apt to think his pet methods are the very best, and more or less inclined to regard his fads as steps towards perfection, if not indeed its full realization, there are a few who take a sounder view of things, and care nothing for novelty for its own sake. The author of the volume before us has shown that he is one of the few. This book is of sterling value, and will be welcomed by the teacher of elementary chemistry as a guide for his students that he will have pleasure and full confidence in placing in their hands. The volume is well got up, printed in clear type, and illustrated with a sufficient number of excellent diagrams, many from original drawings made by the author. Its 272 pages are not crowded with information or anything else, but the facts included are clearly described in a readable and concise manner. In scope, the book includes the principal non-metallic elements and their chief compounds, followed by the more important metals and their salts. The selection is good and not novel. The periodic law is briefly referred to, and the last eighteen pages are occupied with the chemical physics that it is usually considered well for elementary students to master, such as the relation between specific heat and atomic weight, critical temperature, diffusion of gases, effects of temperature and pressure upon gases, and so on.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Alpine Haze.

PROF. TYNDALL has done good service by drawing attention to Alpine haze, and is quite right in adding that it appears in horizontal layers. Such is its common form, but I have also observed a vertical part of it connecting two horizontal striæ rendered conspicuous by concealing portions of a setting sun,



Setting sun observed February 16, 1846, at Garuqqe. in lat. 8° 0'·6, long. 36° 51', at an altitude of 2175 metres.

just as thick boards might do. On another occasion I saw a rough column of it towards the north-west at a supposed distance of three or four kilometres. A few hours later, while I was noting down the phenomenon, a native exclaimed that it had changed its position, and on looking north-west I could see no trace of it, a column similar in size and distance being then in the north-east. It towered above my level on a rolling plain 2300 metres above the ocean. In another place I have seen it at a height of 3600 metres.

Although generally overlooked by meteorologists, this phenomenon has a special name in warm countries. Portuguese call it *neblita*; in Spain it is mentioned as *callina* or *calina*, and Basques name it *lañoa*. Nowhere have I seen it so frequent and thick as in Ethiopia, every different language of that wide region having a special word to express it. The Amara call it *tigag*; the Oromo, or Galla, *qayota*; the Tigray, *taqa*; while old Ethiopic employs the term *qobar*. I have used the latter in my published accounts, because *brume* in French and *haze* in English are generic and not specific names.

Qobar is gray, and of a livid hue when intense, verging sometimes to blackness. The Gascon-speaking population in the Pyrenees call it *bruma terranera*, *i.e.* earth-haze. Its edges are not jagged, like those of clouds, but quite smooth. At Quarata, in 1845, when I was at the level of Lake Tana, the Island of Daga, which rises suddenly 140 metres above the water at an angular height of 16' and a distance of 11·6 miles, was visible only by 4' or 5' of its upper part, the lower 11' or 12' being concealed by *qobar* thicker than usual, and seemingly spread on the lake. I have seen it often on the Red Sea, and sometimes even here in the Bay of Biscay towards the north.

Qobar is the surveyor's foe, and has made me lose several important bearings. It blurs the landscape, diminishes estimated distances, and in Ethiopia is often so thick that no feature of a country is visible beyond the space of a mile.

Fifteen years ago I published in my "Physique du Globe" all that I know about *qobar*. In Germany it goes by the name of *Heiderauch*, or by six other words all ending in "*rauch*." Ethiopians also compare it to but distinguish it from smoke. When commenting on chapter x. of Exodus, their native professors say that the darkness mentioned in verse 22 was an intense *qobar*, and go on to explain that the light enjoyed by the Children of Israel is fully borne out by the fact of *qobar* being sometimes prevalent in one place, yet absent in its neighbourhood. I have noted several instances of this partial occurrence. Without quoting them, I may mention that, according to my working hypothesis, *qobar* is only dry air, visible because in large quantity. On the other hand, astronomers well know that very moist air is the most transparent.

Natives are swarthy in countries where *qobar* abounds. Does it darken man's skin? At all events it is worth while to draw some hundred litres of it through suitable reagents. Chemists could thus test Kaemtz's notion that it is always smoke.

ANTOINE D'ABBADIE (de l'Institut).

Abbadia, Hendaye, November 10.

P.S.—I forgot to mention that, after crossing the three layers shown by the figure, the setting sun crossed two other layers, and finally disappeared behind the lower stratum of *qobar*, then 3° or 4° above the horizon.

Rankine's Modification of Newton's Investigation of the Velocity of Sound in any Substance.

PROF. EVERETT'S letter (November 8, p. 31) calls attention to a difficulty which is apparently felt by students over the attempted elementary method of deducing the general expression for the velocity of sound given in Maxwell's "Heat." Advanced students need feel no difficulty of the kind, because they arrive at it by another path; but inasmuch as the Rankine method seems the easiest available to intermediate students, it is desirable as a matter of pedagogy to put it in its simplest form; and so I venture to quote here the plan I have for some time adopted.

First lead up to the subject by considering the velocity of a hump on a stretched string. Explain the plan of imagining the string to move along at the same pace as the hump, but in an opposite direction, so as to keep the hump stationary in space, obtaining the velocity necessary to do this by equating the normal compound of the tension to the centrifugal force—

$$T \cdot \frac{ds}{r} = \frac{\lambda ds \cdot u^2}{r}, \quad \text{or } u = \sqrt{\frac{T}{\lambda}},$$

where T is the tension, and λ is the linear density of the string; and then actually show the experiment—running a light loose flexible endless cord on a pulley, and making a hump on it. The tension in a loose whirled endless cord free from gravity being that due to the centrifugal force only, viz.—

$$T = \frac{\lambda ds \cdot v^2}{r} \cdot \frac{r}{ds} = \lambda v^2,$$

it follows that $v = u$, and so the keeping of the hump still is automatic, except for a slight interference by the weight of cord hanging below the hump. This interference being less and less notable as the hump is initially made nearer the bottom of the loop of cord.

Next explain, and illustrate by moving diagrams, the simple harmonic motion of the particles of a medium conveying sound-vibrations.

Then proceed to consider a longitudinal pulse travelling along a substance contained in a tube of unit area, and imagine a wind of the substance blowing through the tube in the opposite direction with such a velocity, U, as just to keep the pulse stationary in space.

Except for an unessential disturbance due to friction, the pressure all through the tube is uniform so far as the wind-motion is concerned.

Erect across the tube a couple of imaginary partitions, and watch the substance streaming past them. The state of the substance at either partition, whatever it may be at one instant, remains permanently the same always; hence the mass of substance inclosed between the two must remain permanently the same—for it cannot be always steadily increasing—and therefore the mass of matter flowing through any one plane is constant.

In future attend to one of the planes only, and call the density of the substance at this place ρ. The plane may be at or near a condensation, it may be at or near a rarefaction, or, again, it may be where the substance has its ordinary density; whatever the state of the substance there, the same it remains. The longitudinal-pulse motion of the particles of substance (which has previously been illustrated and discussed at length) is superposed upon the wind-motion; and if we followed any one particle along the stream we should see it simply oscillating with a simple harmonic motion—

$$x = a \sin nt, \quad \text{or} \quad v = an \cos nt,$$

having at any instant the velocity v.

But we are not going to follow a single particle down stream; we are contemplating a procession of particles as they successively pass the fixed partition, and at the instant of passage they are all in a definite phase of their motion—they all have the same definite velocity, v, as they pass, in addition to their general wind-velocity, U. The vibratory velocity v may be in the same direction as U, or it may be in the opposite direction; it may have any value between $\pm na$, of course. So the resultant velocity of each particle as it passes the fixed partition is algebraically $\mathrm{U} + v$. This represents the length of cylinder of substance passing through the partition per second; and, since the partition is of unit area, the mass of substance flowing past it per second is

$$m = (\mathrm{U} + v)\rho, \text{ and is constant} \quad . \quad . \quad . \quad . \quad (1)$$

This of itself is an interesting result; for it shows that at the middle of condensations, where ρ is a maximum, v must have its greatest negative value; and the particles are therefore all in full swing back against the wind (*i.e.* travelling with the sound-pulse) at the middle of every condensation. At a rarefaction, v has its greatest positive value, and the particles are swinging with the wind (against the sound-pulse). Only at half-way places, where the density of the substance has its average or undisturbed value, are the particles quiescent as regards the sound-pulse.

Next consider the dynamics of the matter, and the force which must act to vary the motion of the particles.

If the pressure were the same on either side the partition, there could be no change of velocity for the particles as they pass. The charge of velocity, $d(\mathrm{U} + v)$, or dv, must be due to a difference of pressure existing on either side the partition; and if the slope of pressure $\frac{dp}{dx}$ is positive, the pressure is greater on the lee-side of the partition than on the windward side, and so the acceleration $\frac{dv}{dt}$ will be negative. Hence, equating the force acting and the momentum generated by it per second,—

$$dp = -m dv \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

This equation, along with equation (1), solves the problem, and determines the velocity U.

Differentiating (1)—

$$(\mathrm{U} + v)d\rho + \rho dv = 0.$$

Rewriting (2) by help of (1)—

$$(\mathrm{U} + v)\rho dv = -dp.$$

Substituting for ρdv from one of these into the other, we get—

$$(\mathrm{U} + v)^2 = \frac{dp}{d\rho} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

This equation shows that $\frac{dp}{d\rho}$ is by no means constant all through the substance. It is greatest wherever v has its maximum positive value—that is, at the centre of every condensation; it is least at the centre of every rarefaction; it has an average value in the undisturbed portions of the medium, and it is there equal to U^2.

Hence we learn that the value of U is determined by calculating the ordinary value of $\frac{dp}{d\rho}$ for the medium in its uncompressed and unrarefied state.

So—

$$\mathrm{U} = \sqrt{\frac{dp}{d\rho}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

This is the velocity with which the substance must flow through the tube in order to keep the sound-pulse stationary: this, therefore, is the velocity of sound in it.

The result is general, and applies to all substances. But for gases it may be written more explicitly by help of their characteristic equation $\frac{p}{\rho} = \mathrm{RT}$, and their adiabatic condition $p \propto \rho^\gamma$: viz.—

$$\mathrm{U} = \sqrt{\gamma \mathrm{RT}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

T here means the undisturbed temperature of the gas, but if one chooses to allow the equation to follow the fluctuations of temperature ($\pm t$) adiabatically produced in the condensations and rarefactions, one must write the more general form—

$$(\mathrm{U} + v)^2 = k\mathrm{R}(\mathrm{T} \pm t) \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

which gives us the relation between fluctuation of temperature and vibrational velocity. We may also write it—

$$\rho^2(\mathrm{T} \pm t) = \text{const.} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

which shows the connection between the elevation or depression of temperature, and the density, at any part of a sound-wave.

Speaking as a teacher, I believe one reason why we fail to make things clear is, because we are often in too big a hurry. One's natural tendency is to give such an investigation—as this, for instance, in Maxwell's "Heat"—in a few lines on the blackboard, taking perhaps half an hour or less over it, and forgetting that it embodies in concentrated form a great deal of difficult thought, though the actual mathematics may be simple. Gradually I am learning not thus to scamper over the ground, but to lead up to a thing in two or three or even more lectures, and then to devote a whole hour to the thing itself. By this means, students may ultimately be got to grip and feel the thing as a whole, instead of having to ascend step by step to it; but it is hopeless to expect them to thus grasp it straight off; and even if it were possible, it would not be really desirable for various reasons. The attempt to hurry them into the comprehension of difficulties leads them, I believe, into a vague notion that everything is hazy and half unintelligible. The best thing we can do for them is to get them to see some few things luminously, so that they may not feel inclined to rest satisfied with half-knowledge in other instances.

OLIVER J. LODGE.

November 12.

P.S.—Since writing the above, I have referred to Prof. Everett's note A in Deschanel, and have found it excellent, like all his notes; he happens to have employed just the same means as the above for obtaining equation (1), but for the latter part I prefer my statement. I trust no one will imagine that the above contains anything more than a way of putting things to students.

The slip of a wrong sign in Maxwell I had not distinctly noticed, but the simplest statement of it seems to be that in obtaining the second equation he has put, for the change of velocity of each particle as it passes a plane, du instead of $d(\mathrm{U} - u)$; that is, the change of absolute instead of relative velocity.—O. J. L.

A Simple Dynamo.

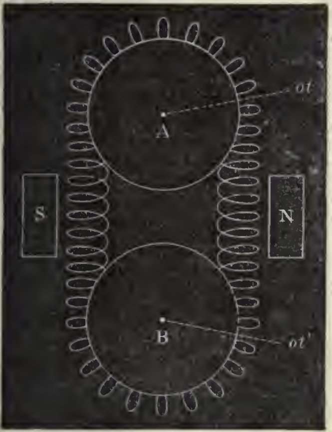
I VENTURE to send you a brief description of a simple electromagnetic instrument which I have recently devised for illustrating the principle of the Gramme ring.

Two pulleys, A, B, having semicircular grooves, are mounted, as shown in the figure, on a piece of board; round the two wheels is stretched a continuous coil of copper wire; a horse-shoe magnet is placed with its poles close to the vertical parts of the coil; the wheels are connected to the terminals t t': when the wheel A is rotated the whole coil moves, and a steady current is at once generated, which flows from terminal to terminal when they are

connected together, the direction of the current depending on the direction of rotation.

It will be noticed that, since the coil and wheels are always in contact, no undulations are produced as when brushes come in contact with successive ends of coils, as in the ordinary dynamo.

When the instrument is placed in circuit with a sensitive galvanometer, the rotation being constant, no variation in the current can be detected, even when the motion is very slow. The coil when arranged with one wheel at A, and a mercury contact at B, will revolve when a current is sent through it, becoming in this case a motor. If an iron chain, or an elastic band of iron such as a measuring tape, be placed inside the ring coil, it then becomes a



distorted Gramme ring, the wheels taking the place of the brushes, the way in which the current is produced being the same. If coils approaching N produce a current upwards, then those which are leaving N produce one downwards. The same takes place on the other side; coils leaving the S pole produce a current upwards, while those which approach it produce a current downwards; both of the ascending currents, being in the same direction, go to the wheel A, while both of the descending currents, being in an opposite direction, go to the wheel B.

The first coil made was of copper wire. Phosphor bronze wire answers better, being less easily distorted.

The Use of Rotifera.

CAN any of your readers inform me whether Rotifers are of any use in removing decaying organic matter, as Infusoria do?

C. L.

ON THE MECHANICAL CONDITIONS OF A SWARM OF METEORITES.[1]

I.

MR. LOCKYER writes in his interesting paper on meteorites[2] as follows:—

"The brighter lines in spiral nebulæ, and in those in which a rotation has been set up, are in all probability due to streams of meteorites with irregular motions out of the main streams, in which the collisions would be almost *nil.* It has already been suggested by Prof. G. Darwin (NATURE, vol. xxxi. p. 25)—using the gaseous hypothesis—that in such nebulæ 'the great mass of the gas is non-luminous, the luminosity being an evidence of condensation along lines of low velocity according to a well-known hydrodynamical law. From this point of view the visible nebula may be regarded as a luminous diagram of its own stream-lines.'"

The whole of Mr. Lockyer's paper, and especially this passage in it, leads me to make a suggestion for the reconciliation of two apparently divergent theories of the origin of planetary systems.

The nebular hypothesis depends essentially on the idea that the primitive nebula is a rotating mass of fluid, which at successive epochs becomes unstable from excess of rotation, and sheds a ring from the equatorial region.

The researches of Roche[1] (apparently but little known in this country) have imparted to this theory a precision which was wanting in Laplace's original exposition, and have rendered the explanation of the origin of the planets more perfect.

But notwithstanding the high probability that some theory of the kind is true, the acceptance of the nebular hypothesis presents great difficulties.

Sir William Thomson long ago expressed to me his opinion that the most probable origin of the planets was through a gradual accretion of meteoric matter, and the researches of Mr. Lockyer afford actual evidence in favour of the abundancy of meteorites in space.

But the very essence of the nebular hypothesis is the conception of fluid pressure, since without it the idea of a figure of equilibrium becomes inapplicable. Now, at first sight, the meteoric condition of matter seems absolutely inconsistent with a fluid pressure exercised by one part of the system on another. We thus seem driven either to the absolute rejection of the nebular hypothesis, or to deny that the meteoric condition was the immediate antecedent of the sun and planets. M. Faye has taken the former course, and accepts as a necessary consequence the formulation of a succession of events quite different from that of the nebular hypothesis. I cannot myself find that his theory is an improvement on that of Laplace, except in regard to the adoption of meteorites, for he has lost the conception of the figure of equilibrium of a rotating mass of fluid.

The object of this paper is to point out that by a certain interpretation of the meteoric theory we may obtain a reconciliation of these two orders of ideas, and may hold that the origin of stellar and planetary systems is meteoric, whilst retaining the conception of fluid pressure.

According to the kinetic theory of gases, fluid pressure is the average result of the impacts of molecules. If we imagine the molecules magnified until of the size of meteorites, their impacts will still, on a coarser scale, give a quasi-fluid pressure. I suggest, then, that the fluid pressure essential to the nebular hypothesis is in fact the resultant of countless impacts of meteorites.

The problems of hydrodynamics could hardly be attacked with success, if we were forced to start from the beginning and to consider the cannonade of molecules. But when once satisfied that the kinetic theory will give us a gas, which, in a space containing some millions of molecules, obeys all the laws of an ideal non-molecular gas filling all space, we may put the molecules out of sight and treat the gas as a plenum.

In the same way the difficulty of tracing the impacts of meteorites in detail is insuperable, but if we can find that such impacts give rise to a quasi-fluid pressure on a large scale, we may be able to trace out many results by treating an ideal plenum. Laplace's hypothesis implies such a plenum, and it is here maintained that this plenum is merely the idealization of the impacts of meteorites.

As a bare suggestion, this view is worth but little, for its acceptance or rejection must turn entirely on numerical values, which can only be obtained by the consideration

[1] Abstract of a Paper read before the Royal Society on November 15 by Prof. G. H. Darwin, F.R.S.

[2] NATURE, November 17, 1887. The paper itself is in the Roy. Soc. Proc., November 15, 1887 (No. 259, p. 117).

[1] *Montpellier Acad. Sci. Mém.*

of some actual system. It is obvious that the solar system is the only one about which we have sufficient knowledge to afford a basis for discussion. The paper, of which this is an abstract, is accordingly devoted to a consideration of the mechanics of a swarm of meteorites, with special numerical application to the solar system.

When two meteoric stones meet with planetary velocity, the stress between them during impact must generally be such that the limits of true elasticity are exceeded, and it may be urged that a kinetic theory is inapplicable unless the colliding particles are highly elastic. It may, however, I think, be shown that the very greatness of the velocities will impart what virtually amounts to an elasticity of a high order of perfection.

It appears, *a priori*, probable that when two meteorites clash, a portion of the solid matter of each is volatilized, and Mr. Lockyer considers the spectroscopic evidence conclusive that it is so. There is no doubt enough energy liberated on impact to volatilize the whole of both bodies, but only a small portion of each stone will undergo this change. A numerical example is given in the paper to show the enormous amount of energy with which we are dealing. It must necessarily be obscure as to how a small mass of solid matter *can* take up a very large amount of energy in a small fraction of a second, but spectroscopic evidence seems to show that it does so; and if so, we have what is virtually a violent explosive introduced between the two stones.

In a direct collision each stone is probably shattered into fragments, like the splashes of lead when a bullet hits an iron target. But direct collision must be a comparatively rare event. In glancing collisions the velocity of neither body is wholly arrested, the concentration of energy is not so enormous (although probably still sufficient to effect volatilization), and since the stones rub past one another, more time is allowed for the matter round the point of contact to take up the energy; thus the whole process of collision is much more intelligible. The nearest terrestrial analogy is when a cannon-ball rebounds from the sea. In glancing collisions fracture will probably not be very frequent.

From these arguments it is probable that, when two meteorites meet, they attain an effective elasticity of a high order of perfection; but there is of course some loss of energy at each collision. It must, however, be admitted that on collision the deflection of path is rarely a very large angle. But a succession of glancing collisions would be capable of reversing the path, and thus the kinetic theory of meteorites may be taken as not differing materially from that of gases.

Perhaps the most serious difficulty in the whole theory arises from the fractures which must often occur. If they happen with great frequency, it would seem as if the whole swarm of meteorites would degrade into dust. We know, however, that meteorites of considerable size fall upon the earth, and, unless Mr. Lockyer has misinterpreted the spectroscopic evidence, the nebulæ do now consist of meteorites. Hence it would seem as if fracture was not of very frequent occurrence. It is easy to see that if two bodies meet with a given velocity the chance of fracture is much greater if they are large; and it is possible that the process of breaking up will go on only until a certain size, dependent on the velocity of agitation, is reached, and will then become comparatively unimportant.

When the volatilized gases cool they will condense into a metallic rain, and this may fuse with old meteorites whose surfaces are molten. A meteorite in that condition will certainly also pick up dust. Thus there are processes in action tending to counteract subdivision by fracture and volatilization. The mean size of meteorites probably depends on the balance between these opposite tendencies. If this is so, there will be some fractures, and some fusions, but the mean mass will change very slowly with the mean kinetic energy of agitation. This view is at any rate adopted in the paper as a working hypothesis. It was not, however, possible to take account of fracture and fusion in the mathematical investigation, but the meteorites are treated as being of invariable mass.

The velocity with which the meteorites move is derived from their fall from a great distance towards a centre of aggregation. In other words, the potential energy of their mutual attraction when widely dispersed becomes converted, at least partially, into kinetic energy. When the condensation of a swarm is just beginning, the mass of the aggregation towards which the meteorites fall is small, and thus the new bodies arrive at the aggregation with small velocity. Hence, initially, the kinetic energy is small, and the volume of the sphere within which hydrostatic ideas are (if anywhere) applicable is also small. As more and more meteorites fall in, that volume is enlarged, and the velocity with which they reach the aggregation is increased. Finally the supply of meteorites in that part of space begins to fail, and the imperfect elasticity of the colliding bodies brings about a gradual contraction of the swarm. I do not now attempt to trace the whole history of a swarm; but the object of the paper is to examine its mechanical condition at an epoch when the supply of meteorites from outside has ceased, and when the velocities of agitation and distribution of meteorites in space have arranged themselves into a sub-permanent condition, only affected by secular changes. This examination will enable us to understand, at least roughly, the secular change as the swarm contracts, and will throw light on other questions.

The foundation for the mathematical investigation in the paper is the hypothesis that a number of meteorites which were ultimately to coalesce, so as to form the sun and planets, have fallen together from a condition of wide dispersion, and form a swarm in which collisions are frequent.

For the sake of simplicity, the bodies are treated as spherical, and in the first instance as being of uniform size.

It is assumed provisionally that the kinetic theory of gases may be applied for the determination of the distribution of the meteorites in space. No account being taken of the rotation of the system, the meteorites will be arranged in concentric spherical layers of equal density of distribution, and the quasi-gas, whose molecules are meteorites, being compressible, the density will be greater towards the centre of the swarm. The elasticity of a gas depends on the kinetic energy of agitation of its molecules, and therefore in order to determine the law of density in the swarm we must know the distribution of kinetic energy of agitation.

It is assumed that when the system comes under our notice, uniformity of distribution of energy has been attained throughout a central sphere, which is surrounded by a layer of meteorites with that distribution of kinetic energy which, in a gas, corresponds to convective equilibrium, and with continuity of density and velocity of agitation at the sphere of separation. Since in a gas in convective equilibrium the law connecting pressure and density is that which holds when the gas is contained in a vessel impermeable to heat, such an arrangement of gas has been called by M. Ritter (*Annalen der Physik und Chemie*, vol. xvi., 1882, p. 166) an isothermal-adiabatic sphere, and the same term is adopted here as applicable to a swarm of meteorites. The justifiability of these assumptions will be considered later.

The first problem which presents itself, then, is the equilibrium of an isothermal sphere of gas under its own gravitation. The law of density is determined in the paper, but it will here suffice to remark that, if a given mass be inclosed in an envelope of given radius, there is a minimum temperature (or energy of agitation) at which isothermal equilibrium is possible. The minimum energy

of agitation is found to be such that the mean square of velocity of the meteorites is almost exactly $\frac{2}{3}$ of the square of the velocity of a satellite grazing the surface of the sphere in a circular orbit.

As indicated above, it is supposed that in the meteor-swarm the rigid envelope, bounding the isothermal sphere, is replaced by a layer or atmosphere in convective equilibrium. The law of density in the adiabatic layer is determined in the paper, and it appears that when the isothermal sphere has minimum temperature the mass of the adiabatic atmosphere is a minimum relatively to that of the isothermal sphere. Numerical calculation shows, in fact, that the isothermal sphere cannot amount in mass to more than 46 per cent. of the mass of the whole isothermal-adiabatic sphere, and that the limit of the adiabatic atmosphere is at a distance equal to 2·786 times the radius of the isothermal sphere.[1]

It is also proved that the total energy, existing in the form of energy of agitation, is exactly one-half of the potential energy lost in the concentration of the matter from a condition of infinite dispersion. This result is brought about by a continual transfer of energy from a molar to a molecular form, for a portion of the kinetic energy of a meteorite is constantly being transferred into the form of thermal energy in the volatilized gases generated on collision. The thermal energy is then lost by radiation.

It is impossible as yet to sum up all the considerations which go to justify the assumption of the isothermal-adiabatic arrangement, but it is clear that uniformity of kinetic energy must be principally brought about by a process of diffusion. It is therefore interesting to consider what amount of inequality in the kinetic energy would have to be smoothed away.

The arrangement of density in the isothermal-adiabatic sphere being given, it is easy to compute what the kinetic energy would be at any part of the swarm, if each meteorite fell from infinity to the neighbourhood where we find it, and there retained all the velocity due to such fall. The variation of the square of this velocity gives an indication of the amount of kinetic energy which has to be degraded by conversion into heat and distributed by diffusion, in the attainment of uniformity. This may be called "the theoretical value of the kinetic energy." It appears that in the swarm, this square of velocity rises from zero at the centre of the swarm to a maximum which is attained nearly half-way through the adiabatic layer, and then diminishes. It is found that the variations of this theoretical value are inconsiderable throughout the greater part of the range. From this it follows that there must be diffusion of kinetic energy from without inwards, and considerations of the same kind show that when a planet consolidates there must be a cooling of the middle strata both outwards and inwards.

We must now consider the nature of the criterion which determines whether the hydrostatic treatment of a meteor-swarm is permissible.

The hydrodynamical treatment of an ideal plenum of gas leads to the same result as the kinetic theory with regard to any phenomenon involving purely a mass, when that mass is a large multiple of the mass of a molecule; to any phenomenon involving purely a length, when the cube of that length contains a large number of molecules; and to any phenomenon involving purely a time, when that time is a large multiple of the mean interval between collisions. Again, any velocity to be justly deduced from hydrodynamical principles must be expressible as the edge of a cube containing many molecules passed over in a time containing many collisions of a single molecule; and a similar statement must hold of any other function of mass, length, and time.

Beyond these limits we must go back to the kinetic theory itself, and in using it care must be taken that enough molecules are considered at once to impart statistical constancy to their properties.

There are limits, then, to the hydrodynamical treatment of gases, and the like must hold of the parallel treatment of meteorites.

The principal question involved in the nebular hypothesis seems to be the stability of a rotating mass of gas; but unfortunately this has remained up to now an untouched field of mathematical research. We can only judge of probable results from the investigations which have been made concerning the stability of a rotating mass of liquid. Now it appears that the instability of a rotating mass of liquid first enters through the graver modes of gravitational oscillation. In the case of a rotating spheroid of revolution the gravest mode of oscillation is an elliptic deformation, and its period does not differ much from that of a satellite which revolves round the spheroid so as to graze its surface. Hence, assuming for the moment that a kinetic theory of liquids had been formulated, we should not be justified in applying the hydrodynamical method to this discussion of stability, unless the periodic time of such a satellite were a large multiple of the analogue of the mean free time of a molecule of liquid.

Carrying, then, this conclusion on to the kinetic theory of meteorites, it seems probable that hydrodynamical treatment must be inapplicable for the discussion of such a theory as the meteoric-nebular hypothesis, unless a similar relation holds good.

These considerations, although of a vague character, will afford a criterion of the applicability of hydrodynamics to the kind of problem suggested by the nebular hypothesis. And certain criteria suggested by this line of thought are found in the paper; they give a measure of the degree of curvature of the average path pursued by a meteorite between two collisions.

After these preliminary investigations, we have to consider what kind of meeting of two meteorites will amount to an "encounter" within the meaning of the kinetic theory.

Is it possible, in fact, that two meteorites can considerably bend their paths under the influence of gravitation, when they pass near one another? This question is considered in the paper, and it is shown that unless the bodies have the dimensions of small planets, the mutual gravitational influence is insensible. Hence, nothing short of absolute impact is to be considered an encounter in the kinetic theory, and what is called the radius of "the sphere of action" is simply the distance between the centres of a pair when they graze, and is therefore the sum of the radii of a pair, or, if of uniform size, the diameter of one of them.

(*To be continued.*)

SOME CURIOUS PROPERTIES OF METALS AND ALLOYS.[1]

THE lecture consisted mainly of experimental demonstrations of the changes induced in metals, either by slight variations in the treatment to which they are subjected or by rendering them impure by the addition of small quantities of metals or metalloids.

Prof. Austen began by pointing out that for centuries the early metallurgists investigated the action of exceedingly small quantities of matter upon masses of metal; and he said that, strange as it may seem, the promulgation, in 1803, of Dalton's atomic theory threw a flood of light upon chemical phenomena, but cast into the shade such investigations as those of Bergman, which dealt with influences

[1] This is one of the results established by M. Ritter in a series of papers in the *Annalen der Physik und Chemie* from 1878 onwards.

[1] Abstract of a Lecture delivered by Prof. W. Chandler Roberts-Austen, F.R.S., at the Royal Institution, on May 11, 1888.

of "traces" upon masses, and the authority of Berthollet was not sufficient to save them from neglect. In this eventful year for science, 1803, the latter published his essay on chemical statics, in which he stated, as a fundamental proposition, that in comparing the action of bodies on each other, which depends "upon their affinities and mutual proportions, the mass of each has to be considered" (English edition, by M Farrell, M.D., 1804, p. 5). His views were successfully contested by Proust, but, as Lothar Meyer says, the influence on chemistry of the rejection of Berthollet's views was remarkable:—"All phenomena which could not be attributed to fixed atomic proportions were set aside as not truly chemical, and were neglected. Thus chemists forsook the bridge by which Berthollet had sought to unite the sister sciences, physics and chemistry." Fortunately, however, in this country there was one chemist who had followed up the line of work indicated by the early metallurgists, for in 1803, the same year as that in which both Berthollet's essay and Dalton's atomic theory were published, Charles Hatchett (Phil. Trans., vol. xciii. p. 43, 1803) communicated to the Royal Society the results of a research which he had conducted, with the assistance of Cavendish, in order to ascertain "the chemical effects produced on gold by different metallic substances when employed in certain" (often very small) "proportions as alloys."

Allusion was then made to the evidence of the passage of metals into allotropic states, and it was shown that, although the importance of the isomeric and allotropic states was abundantly recognized in organic chemistry, it had been much neglected in the case of metals. Special attention was then devoted to the works of Joule and Lyon Playfair, who showed, in 1846, that metals in different allotropic states possessed different atomic volumes, and the lecturer then proceeded to the consideration of the work of Matthiessen, who, in 1860, was led to the view that in certain cases when metals were alloyed they passed into allotropic states, probably the most important generalization which has as yet been made in connection with the molecular constitution of alloys.

Instances of allotropy in pure metals were then shown to the audience, such, for example, as Bolley's lead, which oxidizes readily in air; Schützenberger's copper; Fritsche's tin, which fell to powder when exposed to an exceptionally cold winter; Gore's antimony; Graham's palladium; and allotropic nickel. It was further shown that metals could be obtained in chemically active states under the following conditions:—Joule proved that when iron is released from its amalgam by distilling away the mercury the metallic iron takes fire on exposure to air, and is therefore clearly different from ordinary iron, and is, in fact, an allotropic form of iron. Moissan (*Comptes rendus*, vol. lxxxviii. p. 180, 1879) has shown that similar effects are produced in the case of chromium and manganese, cobalt, and nickel, when released from their amalgams with mercury.

Evidence is not wanting of allotropy in metals released from solid alloys, as well as from fluid amalgams with mercury. Certain alloys may be viewed as solidified solutions, and when such bodies are treated with a suitable solvent, usually an acid, it often happens that one constituent metal is dissolved, and the other released in an insoluble form. Reference was then made to a new alloy of potassium and gold, containing about 10 per cent. of the precious metal. If a fragment of this alloy be thrown upon water, the potassium takes fire, decomposes the water, and the gold is released as a black powder: there is a form of this black or dark-brown gold which appears to be an allotropic modification of gold, as it combines with water to form auric hydride. If this dark gold be heated to dull redness, it readily assumes the ordinary golden colour. The Japanese use this gold, released from gold-copper alloys, in a remarkable way, for they produce, by the aid of certain pickling solutions, a beautiful patina on copper which contains only 2 per cent. of gold, while even a trace of the latter metal is sufficient to alter the tint of the patina.

With regard to theoretical views as to molecular change in metals, special care was given to a description of the work of Prof. W. Spring, of Liége, who had furnished much evidence in support of the view that polymerization of metals—that is, the rearrangement of atoms in their molecules—could take place even in *solid* alloys of lead and tin.

With reference to the passage of metals into allotropic states under slight external influences, it was stated that Debray (*Comptes rendus*, vol. xc. p. 1195, 1880) has given a case of an alloy in which a simple elevation of temperature induces allotropic change in the constituent metals. It is prepared as follows: 95 parts of zinc are alloyed by fusion with 5 parts of rhodium, and the alloy is treated with hydrochloric acid, which dissolves away the bulk of the zinc, leaving a rich rhodium-zinc alloy, containing about 80 per cent. of rhodium. When this alloy is heated *in vacuo* to a temperature of 400° C., a slight explosion takes place, but no gas is evolved, and the alloy is then insoluble in *aqua regia*, which dissolved it readily before the elevation of temperature caused it to change its state. We are thus presented (as the experiment shown to the audience proved) with another undoubted case of isomerism in alloys, the unstable, soluble modification of the alloy being capable of passing into the insoluble form by a comparatively slight elevation of temperature.

The industrial importance of the passage of metals and alloys into allotropic states, and the possibility of changing the mechanical properties of metals by apparently slight influences, were fully dealt with; and the lecture concluded with a detailed description of Prof. Austen's own experiments, which have since been printed in the Philosophical Transactions of the Royal Society, the results showing that very small amounts of metallic impurities exert an extraordinary effect on the tenacity and extensibility of gold, and that small as the amounts of these impurities are, their influence is rigidly controlled by the periodic law of Newlands and Mendelejeff, the deleterious action of a metallic impurity being in direct relation to its atomic volume. The audience was asked "to remember that the knowledge of the kind of facts which had been considered comes to us from very early times, for the influence produced on metals by small quantities of added matter had a remarkable effect on the development of chemistry, mainly by sustaining the belief of the early chemists in the possibility of ennobling a base metal so as to transmute it into gold. This was the object to which they devoted life and health, and laboured with fast and vigil. We inherit the results of their labours, and their prayers have been answered in a way they little anticipated, for, from an industrial point of view, if not from a scientific one, metals are 'transmuted' by traces of impurity. Possibly we are nearing an explanation of the causes which are at work, but the fact remains that iron may be changed from a plastic material, which in ornament can be fashioned into the most dainty lines of flow, into one of great endurance, to which, for the present at least, the defence of the country may be trusted, apparently because armour-plates and missiles owe their respective qualities to the fact that carbon, manganese, and chromium have small atomic volumes."

THE LEONID METEOR-SHOWER, 1888.

AT Bristol rain fell heavily between midday on November 12 and the same time on November 13, a 5-inch gauge registering an inch and eight-tenths, which is by far the greatest downpour of the year within twenty-four hours. In the afternoon of November 13 the clouds broke, and the weather showed a disposition to become more favourable. At night the sky was moderately clear

at times. I began to watch for the return of the Leonids at 15h. 30m., but there were many clouds until about 16h., when the firmament cleared and remained nearly cloudless until 18h. During the $2\frac{1}{2}$ hours I counted 29 shooting-stars, and of these 17 were Leonids; so that the shower was pretty conspicuous. The radiant-point was at 149° + 22°, which is almost identical with the place assigned to it in previous years.

The display was noteworthy for the brilliancy of the individual meteors. I observed a large Leonid fireball at 16h. 56m., and I also saw two Leonids equal to Jupiter and one first magnitude at other times. Their paths were as follow:—

	h. m.			°	°	°	°
Nov. 13 ...	16 41 ...	♃	...	166	+ 34	to 172	+ $37\frac{1}{4}$
	16 56 ...	Fireball	...	$125\frac{1}{2}$	− 22	to 121	− $30\frac{1}{2}$
	17 19 ...	♃	...	252	+ $33\frac{1}{2}$	to $257\frac{1}{2}$	+ 31
	17 46 ...	1	...	175	+ $66\frac{1}{2}$	to 210	+ $75\frac{1}{2}$

All these left bright streaks enduring for several seconds. The fireball at 16h. 56m. was situated very low in the southern sky, and I should not have seen it but for its brilliant flashes, which lit up the whole sky with unusual vividness. It must have been a splendid object in the English Channel and at stations in the north-west parts of France. The fine meteor at 17h. 19m. appears to have been seen also by Mr. Backhouse, at Sunderland. At Bristol it was observed near ϵ Herculis, and very close on the north-east horizon; at Sunderland it was projected near Arcturus, about 15° above the east-by-north horizon, and the most remarkable feature of its display at Sunderland was the durableness of the streak, which continued visible to the naked eye *nine minutes* after the flash which accompanied the outburst of the meteor. A comparison of the observations shows that this bolide at its disappearance was about 37 miles in vertical height above point in the North Sea near lat. $55\frac{1}{4}$° N., long. 3° E.

The recent shower appears to have been decidedly brighter than any other return of the same stream since 1879, when there occurred a very similar display to that which has just been witnessed. There was a large proportion of fine meteors from the Leonid radiant on November 13 of that year, and this seems a characteristic element of the shower.

Mr. Backhouse obtained observations at Sunderland which amply confirm those at Bristol during the apparition of 1888. He says the Leonids were "unusually numerous" on November 13. Between 16h. 48m. and 18h. 14m. he noticed about 14 of them, including one fireball, one equal to Jupiter, two equal to Sirius, and one equal to a first magnitude star. The streaks of the larger meteors belonging to this system are very pronounced in their aspect, and they sometimes brighten up considerably a few seconds after the nuclei have died away.

It is probable that this well-known group will become increasingly active every year until its maximum in 1899.

Bristol, November 17. W. F. Denning.

NOTES.

We understand that Prof. Ray Lankester is a candidate for the post of Deputy-Professor of Human and Comparative Anatomy in the University of Oxford, which has just been created in consequence of the continued illness of Prof. Moseley.

Prof. Giard's lectures at the Sorbonne begin to-day. He is to deal with the general proofs of the doctrine of evolution.

It is expected that the meeting of the International Congress of Anthropology and Prehistoric Archæology, at Paris, in 1889, will be a great success. The Congress was founded at Spezzia in 1865, and held its first session at Neuchâtel in 1866. Many members have already announced their intention of being present at the Paris meeting.

At the ordinary meeting of the Institution of Civil Engineers, on Tuesday, November 13, the President, Sir George B. Bruce, announced that Lord Armstrong, C.B., Past-President, in the belief that the Benevolent Fund attached to the Institution was not adequately supported by the general body of members, and that it needed support, had most generously offered to contribute any sum not exceeding £5000, provided the members among them would raise a similar amount.

At a recent meeting of the Edinburgh International Exhibition Association, the joint Committee appointed by the Association and the executive to consider the best way of disposing of the Exhibition surplus submitted its report. The Committee, among various other proposals, recommended that £1000 should be given to the Scottish Meteorological Society in aid of the Ben Nevis Observatory, and £100 to the Royal Scottish Geographical Society.

A resolute effort is about to be made to secure for North London (comprising the boroughs of Finsbury, Hackney, Islington, and St. Pancras) four great technical institutes. The Central Executive Committee has issued a circular, pointing out the need for these institutions, and appealing for funds. It is supposed that if £200,000 can be raised by private subscriptions a like sum will be contributed by the Charity Commissioners.

The next course of Christmas lectures adapted to a juvenile auditory will be given, at the Royal Institution, by Prof. Dewar, F.R.S., the subject being "Clouds and Cloudland." They will begin on December 27. During the recess the staircases leading from the gallery of the theatre have been considerably altered in order to facilitate more speedy egress.

We have already called attention to the fact that an effort is being made to secure for Bedford College (for ladies), York Place, Baker Street, London, new chemical and physical laboratories. The College has been among the most successful of the institutions which send up graduates to the science degrees at the University of London; but its students have hitherto been severely handicapped by the inadequacy of the laboratory accommodation. The opportunity has occurred of securing fresh building-ground adjoining the College, and plans have been prepared for the proposed additional laboratories. The offer must be definitely made before Christmas, and the estimated expenditure will be at least £3000. The Council do not feel warranted in going forward unless they have at least a considerable portion of this sum promised, for which they are entirely dependent on voluntary contributions. Subscribers' names will be received by the lady-resident at the College. An application for assistance is also being made to the City Companies. Bedford College is the only institution exclusively for ladies which provides first-class practical instruction of this kind.

The work of the United States Fish Commission during the past season seems to have been even more than usually successful. Stations capable of hatching four hundred million codfish-eggs have been established at Gloucester and Wood's Holl; and, according to *Science*, these stations will probably put at least one-fourth of that number of cod-fry into the Atlantic Ocean during the present season. It is expected, therefore, that codfish will soon be more plentiful on the coast of New England than they were years ago, and that a lost industry worth millions of dollars will be restored to that part of the United States.

The Committee on Science and the Arts, of the Franklin Institute, of Pennsylvania, wishes to make known the fact that it is empowered to award, or to recommend the award of, certain medals for meritorious discoveries and inventions which tend to the progress of the arts and manufactures. These medals are:—(1) The Elliott Cresson Medal (gold), founded by the legacy

of Elliott Cresson, of Philadelphia, and conveyed to the Trustees of the Franklin Institute. By the Act of the Institution, May 17, 1849, the Committee on Science and the Arts was designated and empowered to award this medal, and the Committee decided to grant it, after proper investigation and report by a sub-committee, either for some discovery in the arts and sciences, or for the invention or improvement of some useful machine, or for some new process, or combination of materials in manufactures, or for ingenuity, skill, or perfection in workmanship. (2) The John Scott Legacy Premium and Medal (twenty dollars and a medal of copper), founded in 1816, by John Scott, a merchant of Edinburgh, Scotland, who bequeathed to the city of Philadelphia a considerable sum of money, the interest of which should be devoted to rewarding ingenious men and women who make useful inventions. Upon request made to the Secretary of the Franklin Institute, full information will be sent respecting the manner of making application for the investigation of inventions and discoveries; furthermore, the Committee on Science and the Arts will receive and give respectful consideration to reports upon discoveries and inventions which may be sent to it with the view of receiving one or the other of the above-named awards. Full directions as to the manner and form in which such communications should be made, will be sent on application.

THE late Prof. Edward Tuckerman made a choice collection of books and papers relating to lichens, some four hundred numbers in all. These works have been presented by Mrs. Tuckerman, in accordance with her husband's wish, to Amherst College Library; and it is proposed to keep the collection by itself under the name of the "Tuckerman Memorial Library," and to render it worthy of the name by making it as complete as possible in its own department. Some persons interested in this specialty may like to assist in maintaining and completing the collection, on the understanding that it shall always be available to public use. Mr. Wm. I. Fletcher, the Librarian of Amherst College, has therefore issued a notice to the effect that he will be glad to receive contributions, either in money or in material (especially rare monographs that may have escaped Prof. Tuckerman's notice), to this memorial to an eminent scholar and man of science. Whatever money may be contributed will be kept as a fund of which only the income will be employed in making additions to the collection, or in repairs and rebinding. The sum of 1000 dollars would probably suffice as such a fund.

AT the meeting of the Scientific Committee of the Royal Horticultural Society on November 13, Mr. Henslow showed specimens of several species of plants which are propagated by cleistogamous flower-buds. By that means, while retaining a dwarf habit, they are able to multiply very rapidly, and to extend over considerable areas in a tennis-lawn. Although none of them are perennials, they remain so reduced in size that they are not exterminated by the mowing-machine periodically cutting them down. The result is that each species has more or less completely covered certain patches of ground, to the almost entire exclusion of everything else. The plants in question are *Cerastium glomeratum*, *Montia fontana*, *Trifolium procumbens*, *Sagina procumbens*, *Alchemilla arvensis*, *Veronica arvensis*, and *Poa annua*. Mr. Henslow added that he had observed, many years ago, *Trifolium subterranean* flourishing in the same way on the close-cut grass in Kew Gardens, on the site of the present rockery.

EARTHQUAKES occurred at Vyernyi on October 30, at 6 a.m.; at Digne, in the Department of the Lower Alps, on November 1, at 1.36 a.m.; in Sikkim on the 9th inst.; and in various places in California on the 19th inst.

ON the night of Saturday, November 3, about 8 o'clock, the tens of thousands of sheep folded in the large sheep-breeding districts north, east, and west of Reading were taken with a sudden panic, jumping their hurdles, escaping from the fields, and running hither and thither. Early on Sunday morning the shepherds found their animals under hedges and in the roads, panting as if they had been terror-stricken. Messrs. Oakshott and Millard, who write to us on the subject, suggest that a slight earthquake may have been the cause of this strange incident.

THE third general meeting of the Italian Meteorological Society was held at Venice, from September 14 to 21, in the Institute of Music of Benedetto Marcello. Reports of the various papers read are being published in the *Bollettino Mensuale* of the Society. There were discussions on various questions connected with general meteorology and climatology; meteorology applied to hygiene, and hydrology; and geodynamics.

A SUMMARY of the results of two interesting papers read by General Strachey at the recent meeting of the British Association on the meteorology of the Red Sea and Cape Guardafui, prepared from data collected by the Meteorological Office, is contained in the Proceedings of the Royal Geographical Society for November. In 1882 the Admiralty called attention to the precautions necessary in rounding Cape Guardafui from the southward, wrecks having frequently occurred in foggy weather and at night-time, owing to vessels being out of their reckoning from the great variation in the drift of the currents. The paper shows that, although not always infallible, the change of sea temperature in approaching the land is of great assistance in determining the position when near this dangerous coast. The late Captain Symington called attention to this important fact in 1880.

THE Meteorological Office of the Argentine Republic, which was established at Cordoba by Dr. Gould fourteen years ago, and to which we are chiefly indebted for our knowledge of the climate of this vast region, continues to follow the same useful lines under its present Director, Mr. G. G. Davis. Volume vi. of the *Anales*, recently published, contains exhaustive discussions on the climate of five places, from as long a series of observations as was available in each case. The observers are supplied with verified instruments, and the stations are regularly inspected. Several new stations have been established in the more remote districts.

MOST ornithologists have hitherto been of opinion that birds during their yearly migrations never cross the Caucasus chain of mountains, and that on their way towards the north, and on their return, they take the route *viâ* the shores of the Black Sea or of the Caspian. It appears, however, from recent observations made by M. Rossikoff, and communicated to the *Caucasus* newspaper, that such is not the case. On October 9, while on the banks of the Aragva, close by the Ananur station, he saw a number of large birds on the summit of the Tsikhes-dziri Mountain, and they proved to be a flock of some 100 to 150 white storks (*Ciconia alba*), which were crossing the Caucasus chain on their return journey. It appeared also from information gathered from the inhabitants that cranes, herns, and ducks have been often seen in that part of the main chain on their migrations.

TWO new crystalline compounds of arsenious oxide with sodium bromide and sodium iodide have been prepared by Prof. Rüdorff, of Charlottenburg. They form two additional members of an interesting isomorphous group discovered two years ago by Prof. Rüdorff, having the general formula $MX + 2As_2O_3$, where M may be potassium, sodium, or ammonium, and X represents chlorine, bromine, or iodine. In his former memoir, published in 1886, the following members of the series are described, and accurate analyses given:—$KI + 2As_2O_3$, $KBr + 2As_2O_3$, $KCl + 2As_2O_3$, $NH_4I + 2As_2O_3$, and $NH_4Br + 2As_2O_3$. These five salts are beautifully isomorphous,

forming hexagonal prisms with rhombohedral terminations, almost undistinguishable from each other on account of their extreme similarity. The two new compounds just announced in the current *Berichte* are the sodium compounds $NaBr + 2As_2O_3$ and $NaI + 2As_2O_3$. The former was obtained by dissolving 20 grammes arsenious oxide and 120 grammes sodium bromide in 350 c.c. boiling water, filtering the somewhat turbid liquid thus obtained, and allowing the clear solution to cool very slowly. On suspending in it a plate of cold glass, crystals of the compound were immediately deposited upon it, which proved on microscopic examination to consist of the hexagonal prisms common to the whole series. The crystals were then washed upon the large glass plate with cold water, dried superficially between filter-paper, afterwards at 130°, and submitted to analysis. The numbers obtained indicate the formula given above. The crystals, as in the case of many other double compounds, are decomposed into their constituents by contact with warm water. The second compound, $NaI + 2As_2O_3$, was similarly obtained, using 60 grammes sodium iodide, 22 grammes arsenious oxide, and dissolving them in half a litre of hot water. On allowing a glass plate to stand twenty-four hours in the solution, it was found to be covered with six-sided prisms, apparently identical in shape with those of the other compounds of the series previously obtained. It is interesting that both these compounds can be readily obtained by the addition of a sufficient quantity of bromide or iodide of sodium to a solution of sodium arsenite. The corresponding compound with chloride of sodium has not yet been prepared. Thus another series of analogous salts is added to the list of isomorphous groups, the number of which is steadily increasing. These groups are of especial interest to the crystallographer, inasmuch as they appear likely to be of invaluable assistance in our attempts to grasp the fundamental problem, "Why does a definite chemical compound crystallize in any particular system?"

THE County of Middlesex Natural History and Science Society has issued its Transactions during the session 1887–88. The volume includes, besides an abstract of an introductory address by Dr. Archibald Geikie, papers on subjects of scientific interest by Prof. Flower, Mr. W. Lant Carpenter, Dr. Sydney T. Klein, and others.

THE new number of the Journal of the Anthropological Institute (vol. xviii. No. 2) is one of great interest. Mr. Galton offers some suggestive remarks on replies by teachers to questions respecting mental fatigue, and Mr. J. Venn has a careful paper on "Cambridge Anthropometry." In a paper on the races of the Babylonian Empire, Mr. G. Bertin sets forth some conclusions which are so different from, and even opposed to, "accepted notions," that he hesitated a long time, he says, "before surrendering himself to the evidence."

DR. H. TEN KATE, in a letter to *Science*, expresses dissent from the opinions lately set forth by Dr. Daniel G. Brinton, as to "the alleged Mongolian affinities of the American race." Dr. Brinton holds that there are no such affinities, whereas to his opponent it seems obvious that the native race of America cannot be properly understood without reference to the Mongolians. Summing up his views on the subject, Dr. H. Ten Kate says:—"I wish to say that Dr. Brinton's argumentation against the affinity between Americans and Mongolians is based upon entirely wrong reasoning. If the reasons he gives were correct, then the classification of the other races of the human species would be equally wrong; for in each of them peoples are grouped together, which, although related by physical characteristics, are linguistically and ethnologically entirely different from each other, not to speak of the difference in their psychological and social evolution. When I admit that the native Americans are Mongoloids, I do not necessarily imply that America has been populated from Asia or elsewhere. However, if we accept the theory of evolution, this is the most probable explanation of the observed facts. But, leaving the doubtful origin of the Americans, and of their languages and arts, out of the question, I maintain that there is a physical similarity, racial affinity, and relationship between the indigenous Americans and the Mongolians in the widest sense. This is, in the present state of anthropological knowledge, an undeniable fact. He who denies it does not believe in physical anthropology; and not to recognize this branch of science is equal to denying natural history in general."

IN the last Administration Report of the Island of Dominica, which has just been laid before Parliament, the President estimates the original Carib population at about three hundred, or something under that figure. The children are healthy, and the numbers of Caribs, according to their own accounts, are not decreasing, but they are gradually becoming so intermixed with the Negroes that the pure Carib, "Franc Carib," will soon be non-existent. The Carib quarter, a reserve of large extent on the Windward side of Dominica, is wholly occupied by them. They are very peaceable and retiring; they live on vegetables and fruits, which they cultivate, and on fish. They keep their roads in good order. Their children appear to be very intelligent, but there is no school in the Carib quarter, though the people are very anxious to have one.

A SOCIETY has been formed in France, under the patronage of many men of high scientific and political standing, for the purpose of developing a proper system of physical education. The leader of the new movement is M. Philippe Daryl, *alias* Paschal Grousset, who, when a very young man, took an active part in the Paris insurrection of 1871. He afterwards lived in England, whence he sent interesting letters to the *Temps*.

THE *Madras Mail* says that Dr. Thurston, the Superintendent of the Madras Museum, has been requested by the Board of Revenue to visit various electrical establishments in Europe in order to select an electric globe light to shine in twenty fathoms of water. Such a light has long been wanted at the pearl fisheries, for, up to the present, the work of the fisheries has been confined to banks situated at a less depth than twenty fathoms.

THE next *conversazione* of the Royal Microscopical Society will be held on Wednesday, the 28th instant, at 8 o'clock.

THE additions to the Zoological Society's Gardens during the past week include a —— Monkey (*Cercopithecus* sp. inc.) from South Africa, presented by Mr. L. B. Lewis; an Indian Antelope (*Antilope cervicapra* ♂) from India, presented by Mr. J. W. Shand-Harvey; a Himalayan Bear (*Ursus tibetanus* ♀) from Northern India, presented by the Regiment of the 2nd Life Guards; an Axis Deer (*Cervus axis*) from India, presented by Lady Donaldson; a Roseate Cockatoo (*Cacatua roseicapilla*) from Australia, presented by Mrs. Wood; two American Bitterns (*Botaurus lentiginosus*) from North America, presented by Mr. J. B. Williams; a Peregrine Falcon (*Falco peregrinus*), captured at sea, presented by Mr. R. H. Armstrong; a Spotted Salamander (*Salamander maculosa*), European, presented by Mr. F. E. B. Roper, F.Z.S.; two Swans (*Cygnus olor* ♀ ♀), European, a Royal Python (*Python regius*) from West Africa, deposited; two Golden Plovers (*Charadrius pluviatilis*), British, purchased.

OUR ASTRONOMICAL COLUMN.

THE BRAZILIAN TRANSIT OF VENUS EXPEDITIONS, 1882.—We have received vol. iii. of the "Annaes do Imperial Observatorio do Rio de Janeiro," containing the reports of the

Brazilian expeditions to observe the transit of Venus of December 1882. The volume, which is a handsome quarto of some 750 pages, and is fully illustrated with photographs of the various stations and instruments, contains reports from three stations, the weather at the Imperial Observatory at Rio de Janeiro itself, which should have been a fourth station, having proved cloudy and wet. It had been at first intended to send an expedition to Cuba, but as the French astronomers were to occupy a position there, the little Island of St. Thomas, belonging to Denmark, was chosen instead. St. Thomas paired well with the southern station, Punta Arenas, in Patagonia, for the duration was much shortened at the former place and slightly lengthened at the latter, the sun being high at both stations, and ingress and egress at both taking place nearly symmetrically with regard to the meridian. The entire transit was also seen from the remaining station, Olinda, near Pernambuco, where ingress was somewhat retarded and egress much accelerated. The observations were all made by the method of projection, in order that the disturbing effects of irradiation might be got rid of as far as possible. The St. Thomas expedition which was under the command of Baron de Teffé, possessed three equatorials, and Dr. H. Draper had promised to supply a photo-heliograph, but his lamented death prevented the carrying out of his generous intention. The Olinda expedition, commanded by M. J. de Oliveira Lacaille, had two equatorials; whilst M. Cruls, the chief of the Punta Arenas party, had but one; the largest telescope in each case being 6¼ inches in aperture. M. Cruls selected a site for his party within a mile of that occupied by Dr. Auwers with the German expedition; for the Brazilian Parliament having delayed the necessary credit for the expedition to the last moment, the expedition did not arrive at the place until late, and it seemed better to take advantage of the German choice of position rather than lose time by surveying for a fresh site at a distance. The observations at each of these three stations were successful, the second internal contact being observed at all, but the first internal contact was lost at St. Thomas. The method of chords could not, therefore, be employed, but the combination of the second contacts of the two northern stations with both contacts of the southern gave 8″·808 as the resulting parallax. A large part of the volume is devoted to a report of the voyage of the corvette *Parnahyba*, by Captain L. Saldanha de Gama, the captain who conveyed the southern observing party to their station, and to a description of the natural history of Tierra del Fuego.

The Tail of Comet 1887 *a* (Thome).—Prof. Bredichin has discussed in the *Bulletin* of the Imperial Society of Naturalists of Moscow, 1888, Nos. 2 and 3, the observations of the direction of the tail of this comet. The comet was discovered by Mr. Thome, of Cordoba, on January 18, 1887, and it was remarkable for the smallness of its perihelion distance, the complete absence of any nuclear condensation in the head, and the length, straightness, and narrowness of the tail. Prof. Bredichin finds that the tail manifestly belongs to his third type, viz. those in which the repulsive force, $1-\mu$, does not exceed 0·1. He suggests, as the rate of outflow in comets of short perihelion distance is much more rapid at perihelion passage than later, and as the comet was not discovered until a week after perihelion, that the lighter materials may already have been driven off and reduced to such a degree of tenuity as to be invisible, leaving only substances of heavy atomic weight. As is well known, he associates his first type of tail, that in which the repulsive force is greatest, with hydrogen, the more ordinary second type with the hydrocarbons; and he suggests in the case of the present comet that elements with atomic weights like those of gold, mercury, and lead, would furnish a tail of the character observed. Some comets, however, which do not approach the sun closely, have tails only of the third type. If, then, Prof. Bredichin's explanation is to be received in its entirety, hydrogen and hydrocarbons are not always constituents of cometary tails.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 NOVEMBER 25—DECEMBER 1.

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on November 25

Sun rises, 7h. 38m.; souths, 11h. 47m. 19·0s.; sets. 15h. 57m.: right asc. on meridian, 16h. 6·7m.; decl. 20° 54′ S. Sidereal Time at Sunset, 20h. 17m.

Moon (at Last Quarter November 26, 17h.) rises, 21h. 1m.*, souths 4h. 56m.; sets, 12h. 40m.: right asc. on meridian, 9h. 14·7m.; decl. 18° 7′ N.

Planet.	Rises.	Souths.	Sets.	Right asc. and declination on meridian.	
	h. m.	h. m.	h. m.	h. m.	° ′

Meteor-Showers.

The most interesting periodical shower of the week is that of the *Andromedes*, the stream connected with Biela's comet, but no remarkable display can be expected from it this year: max. Nov. 27; radiant about R.A. 25°, Decl. 44° N. Other showers of the week are as follow:—

	R.A.	Decl.	
Near λ Persei	60° ...	50 N. ...	Very swift.
,, β Canum Venaticorum	190 ...	42 N. ...	Swift; streaks.

GEOGRAPHICAL NOTES.

Two letters relating to Dr. Nansen's expedition across Greenland have been published—one from Dr. Nansen himself to Mr. Augustin Gamel, Copenhagen, who is defraying the expenses of the expedition; the other from Mr. Sverdrup, one of Dr. Nansen's companions, to his father. The letters were sent forward from Godthaab by two *kajak*-men, who delivered them to the captain of the *Fox*, at Ivigtut. The following is a translation of Dr. Nansen's letter:—

Godthaab, *October* 4.

I have at last the great joy to report to you that Greenland has been successfully crossed from east to west. I regret that the very short time left to me before despatching my messengers will not permit any detailed account. I can just jot down a few words to be forwarded by the *kajak*-men. I am sending southwards in the hope of stopping the *Fox* at Ivigtut, and getting her to wait for us and take us home this autumn. But

in case the *kajak*-messenger should catch the steamer without inducing her to wait for us, I write these few lines just to inform you that we are all alive and well.

As you will know, we left the *Jason*, the Norwegian sealer, on July 17, and expected to reach the shore the next day. But in this we were sadly disappointed. Screwing ice, maëlstroms, impassable ice, where it was alike impossible to row or to drag the two boats, stopped us. One of the boats was stove in, but we got it repaired again. We drifted seawards at a speed of thirty sea miles in the twenty-four hours. Drifted in the ice for twelve days. Strove hard to get to the shore, were three times on the point of succeeding, but were as often carried out to sea again by a current stronger than our power of rowing. Were once, for a whole day and night, very near perishing in tremendous breakers of the sea against the ice-rim. After twelve days' drifting about, we managed at last to get ashore near Andretok, north of Cape Farewell, at 61° and some minutes of northern latitude. We rowed again northwards, reaching Uminik, from which point the crossing of the inland ice began on August 15.

We directed our course for Christianshaab on the western coast. Encountered severe snowstorms and had heavy ground. Estimating that it would be too late to reach Christianshaab in time for this autumn's vessel, we altered our course and steered for Godthaab, the ice-fields in that direction having, besides, been hitherto trodden by no one. After altering course, reached height of 10,000 feet, with temperature of 40° to 50° C. below zero. For several weeks we remained at an altitude of over 9000 feet. Tremendous storms, loose, new-fallen snow, enormously difficult passage. Towards end of September we reached at last the western side above Godthaab. Had a perilous descent, on ugly and very uneven ice, but got safely down to Ameralik Fjord. Managed to build a kind of boat from floor of tent, bags, bamboo reeds, and willow branches. In that frail craft Sverdrup and I rowed away, and arrived here on October 3. The four men are left at Ameralik, living there on short rations fare, but will be sent for as soon as possible.

There you have in short outline our Saga. We are all perfectly well, and everything has been in the best order. I hope that we may catch this steamer, and that instead of this letter you may see our sunburnt faces.

With many greetings, yours ever devotedly,

FRITHIOF NANSEN.

P.S.—Just now the *kajak*-men must leave, profiting by the favourable weather. They have 300 miles to make before getting to Ivigtut.

The following is a translation of Mr. Sverdrup's letter :—

GODTHAAB, *October* 4, 1888.

We arrived safely here yesterday after forty-six days' wandering from east to west. It did not prove so easy to get on shore from the *Jason* as we had expected. We got into formidable ice-screwings, and the current took us southwards and out from the shore, so that we had twelve days' very hard work before getting to land, and that 300 miles more to the south than we had intended. We began at once to work back along the coast, and this took us another twelve days, so that we did not begin our crossing of the ice before August 15. The ascent was very fortunate, as we chanced to find comparatively easy ice to climb up. We shaped our course for Christianshaab, but after getting up to 7500 feet we were attacked by a northern snowstorm. We resolved, therefore, to set our course for Godthaab, the distance being shorter, and there being a better chance of favourable winds. I may truly say that we had a hard time of it. The snow and ice were very heavy, and the weather was trying. For nearly three weeks we were up at nearly 10,000 feet, and had a temperature of −40° to −50° C. Only for four days were we snowbound. After all, we have to be thankful it was not worse. After getting down from the inland ice on the western coast, we had before us some ninety miles of barren country, of which the half lay along a fjord. We tried to cross here, but found it too hard work ; so we managed to construct a kind of boat from the bottom of the tent and some bags, and in that, after four days' rowing, Dr. Nansen and I reached here, where we had the most cordial reception from all the inhabitants of the colony. Two boats have now been sent to the bottom of the fjord to fetch our comrades. The regular vessel has long since left, but some 250 or 300 miles further south there is supposed to be, at Ivigtut, a steamer loading for Copenhagen, and we are now sending a *kajak*-message in order to stop that steamer if possible. We have but little hope of that, however, and are preparing to pass the winter here. That may be very comfortable after all, but of course we would prefer getting home. I must hurry up, as we are now going to dine with the parson, and, in fact, we have not had time for anything, as since arriving here we have gone from one social party to another. You may see from that how well we are off. I was the only one of our whole party who got over all the tremendous fatigues without the smallest ailment. I am, and have been all the time, as fresh and sound as a fish.

DR. GEORG SCHWEINFURTH has started upon an Oriental journey. He is going to Arabia first, to continue his studies of the coffee-plant.

THE FOUNDATION-STONES OF THE EARTH'S CRUST.[1]

DO we know anything about the earth in the beginning of its history—anything of those rock masses on which, as on foundation-stones, the great superstructure of the fossiliferous strata must rest? Palæontologists by their patient industry have deciphered many of the inscriptions, blurred and battered though they be, in which the story of life is engraved on the great stone book of Nature. Of its beginnings, indeed, we cannot yet speak. The first lines of the record are at present wanting—perhaps never will be recovered. But apart from this—before the grass, and herb, and tree, before the "moving creature in the water," before the "beast of the earth after his kind,"—there was a land and there was a sea. Do we know anything of that globe, as yet void of life? Will the rocks themselves give us any aid in interpreting the cryptogram which shrouds its history, or must we reply that there is neither voice nor language, and thus accept with blind submission, or spurn with no less blind incredulity, the conclusions of the physicist and the chemist?

The secret of the earth's hot youth has doubtless been well kept. So well that we have often been tempted to guess idly rather than to labour patiently. Nevertheless we are beginning, as I believe, to feel firm ground after long walking through a region of quicksands; we are laying hold of principles of interpretation, the relative value of which we cannot in all cases as yet fully apprehend—principles which occasionally even appear to be in conflict, but which will some day lead us to the truth.

I shall not attempt to give you an historical summary, but only to lay before you certain facts for which I can answer, and to indicate the inductions which these, as it seems to me, warrant. If I say little of the work of others, it is not from a desire of taking credit to myself, but because it is immaterial for my present purpose who first made a particular observation and how far his inductions therefrom were correct. The acknowledgment of good work would involve repudiation of bad, and for that, so far as persons are concerned, it seems hardly fair to use the present occasion. So, in the outset of this lecture, I will once for all make a statement which I have sometimes thought of invariably using, like a prefatory invocation, "You are free to suppose that everything herein has been said by somebody, somewhere," but I will add that, as far as possible, every assertion has been personally verified.

The name Cambrian has been given to the oldest rocks in which fossils have been found. This group forms the first chapter in the first volume, called Palæozoic, of the history of living creatures. Any older rocks are provisionally termed Archæan. These—I speak at present of those indubitably underlying the Cambrian—exhibit marked differences one from another. Some are certainly the detritus of other, and often of older, materials—slates and grits, volcanic dust and ashes, even lava-flows. Such rocks differ but little from the basement-beds of the Cambrian; probably they are not much older, comparatively speaking. But in some places we find, in a like position, rocks as to the origin of which it is more difficult to decide. Often in their general aspect they resemble sedimentary deposits, but they seldom retain any distinct indications of their original fragmental constituents. They have been metamor-

[1] An evening discourse, delivered at the Bath meeting of the British Association, by Prof. T. G. Bonney, D.Sc., LL.D., F.R.S., &c

phosed, the old structures have been obliterated, new minerals have been developed, and these exhibit that peculiar orientation, that rudely parallel arrangement, which is called foliation. Except for this some masses are fairly homogeneous, while some exhibit a distinct mineral banding which is usually parallel with the other structure. These rocks are the gneisses and schists—the latter term, often vaguely used, I always restrict to rocks which exhibit a true foliation. In some schists the mineral constituents are comparatively minute, in others they are of considerable size. In the former case we may often venture to affirm that the rock is a metamorphosed sediment; in the latter its original condition is a matter of conjecture. Rocks of the former class often appear, to use no stronger word, to lie above, and so to be less ancient than those of the latter, and beneath that comes a coarser and more massive series, in which granitoid rocks are common. In these last foliation is often inconspicuous, and the rocks in consequence are not markedly fissile.

That these rocks are older than the Cambrian can often be demonstrated. Sometimes it can even be proved that their present distinctive character had been assumed before the overlying Cambrian rocks were deposited. Such rocks, then, we may confidently bring forward as types of the earth's foundation-stones. As the inscriptions buried in the Euphrates Valley tell us the tongue of Accad in the days prior to the coming of the Semite, so these declare what then constituted the earth's crust. If in such rocks we find any peculiarities of mineral composition or structure, these may legitimately be regarded as distinctive. We have only to beware of mistaking for original those which are secondary and subsequently impressed.

In other parts of the world we find rocks of like characters with those above named, the age of which cannot be so precisely fixed, though we can prove them to be totally disconnected from and much older than the earliest overlying stratum. To assert that these rocks are contemporary with the others is obviously an hypothesis which rests on the assumption that community of structure has some relation to similarity of origin. I am well aware that attempts have been made to discredit this. But if we eliminate difficulties which are merely sophistical—those, I mean, created by the use of ambiguous or misleading terms—if we acknowledge those due to our limited means of investigation, such as that of distinguishing a rock crushed *in situ* from one composed of transported fragments—in other words, of separating in every case a superinduced from a primary structure, and if we allow for others due to the limitation of our instrumental and visual powers, I do not hesitate, as the result of long and, I hope, careful work, to assert that certain structures are very closely related to the past history of a rock, and that in very many instances our diagnosis of the cause from its effect is not less worthy of confidence than that of an expert in pathology or physiology. Resemblances of structures, different in origin, do, no doubt, sometimes occur—resemblances not seldom due to partial correspondence in the environments; but in regard to these it is our duty to labour patiently till we succeed in distinguishing them. The difficulty of the task does not justify us, either in abandoning it in despair, or in sitting down, after a few hasty observations, to fashion hypotheses which have no better foundation than our own incompetence or idleness.

As it is impossible in the time at my disposal to demonstrate the proposition, I must assume what I believe few, if any, competent workers will deny, that certain structures are distinctive of rocks which have solidified from a state of fusion under this or that environment; others are distinctive of sedimentary rocks; others again, whatever may be their significance, belong to rocks of the so-called metamorphic group. I shall restrict myself to indicating, by comparison with rock structures of which the history is known, what inferences may be drawn as to the history of the last-named rocks, which, as I have already stated, are in some cases examples of the earth's foundation-stones, while in others, if they are not these, they are at any rate excellent imitations.

Let us proceed tentatively. I will put the problem before you, and we will try to feel our way towards a solution. Our initial difficulty is to find examples of the oldest rocks in which the original structures are still unmodified. Commonly they are like palimpsests, where the primitive character can only be discerned, at best faintly, under the more recent inscription. Here, then, is one of the best which I possess—a Laurentian gneiss from Canada. Its structure is characteristic of the whole group; the crystals of mica or hornblende are well defined, and commonly have a more or less parallel arrangement; here and there are bands in which these minerals are more abundant than elsewhere. The quartz and the felspar are granular in form; the boundaries of these minerals are not rectilinear, but curved, wavy, or lobate; small grains of the one sometimes appear to be inclosed in larger grains of the other. Though the structure of this rock has a superficial resemblance to that of a granite of similar coarseness, it differs from it in this respect, as we can see from the next instance, a true granite, where the rectilinear outline of the felspar is conspicuous. Here, then, is one of our problems. This difference of structure is too general to be without significance. What does it mean?

It is more difficult to obtain examples of schist of like geological age, wholly free from subsequent modification. Apparently the structure and composition of the rock have rendered it more liable to disturbance. But those exhibited, though by no means perfect examples, may serve to indicate the structure of an Archæan schist, consisting mainly of quartz and mica. We may take them as representative of a considerable series of rocks, which are often associated in such a manner as to suggest that, notwithstanding their present crystalline condition, they had a sedimentary origin. Can this inference be justified?

How shall we attack this problem? Clearly, the most hopeful way is by proceeding from the known to the unknown. Now, among the agents of change familiar to geologists, three are admittedly of great importance; these are water, heat, and pressure. As probably almost all changes in nature, with which we have to deal, have occurred in the presence of water, but those due to it alone are generally superficial, I shall assume its presence, and not attempt to isolate its effects. But we must endeavour to ascertain the results of pressure and heat, when acting singly and in combination, in modifying rocks of a known character; admitting, however, that probably while the one agent has been dominant, the other has not been wholly inoperative.[1]

The first effect of pressure due to great earth-movements is to flatten somewhat the larger fragments in rocks, and to produce in those of finer grain the structure called cleavage. This, however, is a modification mainly mechanical. It consists in a re-arrangement of the constituent particles, mineral changes, so far as they occur, being quite subordinate. But in certain extreme instances the latter are also conspicuous. From the fine mud, generally the result of the disintegration of felspar, a mica, usually colourless, has been produced, which occurs in tiny flakes, often less than one-hundredth of an inch long. In this process, a certain amount of silica has been liberated, which sometimes augments pre-existing granules of quartz, sometimes consolidates independently as microcrystalline quartz. Carbonaceous and ferruginous constituents are respectively converted into particles of graphite and of iron oxide. Here is an example of a Palæozoic rock, thus modified. It originally consisted of layers of black mud and gray silt. In the former, this filmy mica has been abundantly developed; it is present also, as we might expect, to some extent in the latter. Observe that the original banded structure, notwithstanding the pressure, has not been obliterated. Another point also demands notice. The black lines in the section indicate the direction of the cleavage of the rock, which is, roughly speaking, at right angles to the pressure which has most conspicuously affected the district, while the microfoliation, as we may call it, appears to be parallel to the original bedding, and is thus anterior to the dominant cleavage. The two may form parts of a connected series of movements, but, at any rate, they are so far separated that the pressure which produced the one, acted, roughly speaking, at right angles to that which gave rise to the other, and the folia were developed before they were bent and torn.

Let us now pass on to examine the effects of pressure when it acts upon a rock already crystalline. Here, obviously it is comparatively unimportant whether the original rock was a true granite or a granitoid gneiss; for at present we are only concerned with the effect of pressure on a fairly granular crystalline rock. But in the resultant structures there are, as it seems to me, differences which are dependent upon the mode in which pressure has acted. They are divisible into two groups: one indicating the result of simple direct crushing, the other of crushing accompanied by shearing. In the former case, the rock

[1] Heat will, of course, result from the crushing of rock. This some consider an important factor in metamorphism, but I have never been able to find good evidence in favour of it, and believe that as a rule the rocks yield too slowly to produce any great elevation of temperature.

mass has been so situated that any appreciable lateral movement has been impossible; it has yielded like a block in a crushing-machine. In the latter, a differential lateral movement of the particles has been possible, and it has prevailed when (as in the case of an overthrust fault) the whole mass has not only suffered compression, but also has travelled slowly forward. Obviously, the two cases cannot be sharply divided, for the crushing up of a non-homogeneous rock may render some local shearing possible. Still it is important to separate them in our minds, and we shall find that in many cases the structure, as a whole, like the cleavage of a slate, results from a direct crush; while in others the effects of shearing predominate. The latter accordingly exhibit phenomena resembling the effects of a tensile stress. Materials of a like character assume a more or less linear arrangement, the rock becomes slightly banded, and exhibits, as has been said, a kind of fluxion structure. This phrase, if we are careful to guard ourselves against misconception, is far from inappropriate. The mass gradually assumes a fragmental condition under the pressure, and its particles as they shear and slide under the effects of thrust, behave to some extent like those of a non-uniform mass of rock in a plastic condition, as, for example, a slaggy glass. But we must be on our guard, lest we press the analogy too far. The interesting experiments which have been made on the flow of solids, and on rolled-out plastic substances, while valuable as illustrations, represent, as it seems to me, a condition of things which must be of rare occurrence in a rock mass, pulverized by mechanical forces only. If I am to reason from them, I must regard the rock not as a fragmental solid—if the phrase be permissible—but as an imperfect fluid; that is to say, I must consider them as illustrative of structures in rocks which have yet to assume—not have already assumed—a crystalline condition.

Illustrations of the effects of direct crushing in a granitoid rock are common in the Alps. Those of a shearing crush are magnificently developed near the great overthrust faults in the north-west Highlands of Scotland.

In the former case, where a granitoid rock has been affected only to a moderate extent, and the resulting rock in a hand specimen would be called a gneiss without any very definite mineral banding, we find that under the microscope it exhibits a fragmental structure, the felspars are often somewhat rounded in outline, are frequently rather decomposed and speckled with minute flakes of white mica of secondary origin, and commonly seem to "tail off" into a sort of stream of microlithic mica, which has doubtless resulted from the destruction of felspar, the residual silica making its appearance as minutely crystalline quartz. The original quartz grains have been broken up, and are now represented by smaller grains, often in rudely lenticular aggregates, like little "inliers" of quartzite. The original flakes of black mica have been tattered and torn, and now appear as streaky clusters of flakelets, often less than one-sixth the original length. In extreme cases of crushing, the felspar has almost disappeared; the constituents are all reduced in size, and the rock at first sight would no longer be called a gneiss, but a fine-grained mica-schist. It has become extremely fissile, and the flat faces of the fragments exhibit a peculiar sheen, as if it had received a varnish of microlithic mica. In short, from a granitoid rock a microcrystalline mica-schist has been produced, which, however, differs markedly from the rock to which that name is ordinarily applied.

Let us now turn to a rock of similar nature, in which the effect of shearing is more conspicuous. I have selected a specimen, in which, as in the first example above, some of the felspar still remains in recognizable fragments. These, however, are commonly destitute of the "tail" of mica-microliths, and bear, at first sight, some resemblance to the broken porphyritic felspars which occur in a rhyolite. The mica, whether primary, but fragmental, or secondary, tends to get associated in undulating layers; the quartz also has a more uniform aspect and a more linear arrangement. In the most extreme cases the felspar all but disappears (though I fancy that it has here a better chance of surviving), the quartz and the mica are more and more aggregated in definite but thin bands, and the former, when viewed with crossing nicols, exhibits streaks, which, for a considerable distance, are almost uniform in tint, as if its molecules under a stress definite in direction had acquired a polarity, so that groups of these act upon light almost like a single crystal.

The effects of mechanical deformation, followed by mineral change, are also remarkably conspicuous in the case of pyroxenic rocks. Augite, it is well known, is by no means a stable mineral, and under certain circumstances is readily transformed into hornblende. This occurs in more than one way without mechanical action, but of these I do not now speak. Only of late years, however, has it been known that pressure can convert a dolerite into a hornblende-schist. Of this, through the kindness of Mr. Teall, who first proved the occurrence of this alteration in Great Britain, I can show you an example. The rock, as you see, has lost the structures of a dolerite, and has assumed those characteristic of many hornblende-schists. I say of many, because, though the rock is distinctly foliated, it does not exhibit a conspicuous mineral banding. My own observations confirm those of Mr. Teall, though I have never been so fortunate as to obtain, as he did, a complete demonstration of the passage from the one rock to the other.

It seems, then, to be demonstrated that, by mechanical deformation, accompanied or followed by molecular re-arrangement, foliated rocks, such as certain gneisses and certain schists, can be produced from rocks originally crystalline. But obviously there are limits to the amount of change. The old proverb, "You cannot make a silk purse of a sow's ear," holds good in this case also. To get certain results, you must have begun with rocks of a certain character. So that it is often possible, as I believe, to infer not only the nature of the change, but also that of the original rock. Hitherto we have been dealing with rocks which were approximately uniform in character, though composed of diverse materials—that is, with rocks more or less granular in aspect. Suppose, now, the original rock to have already acquired a definite structure—suppose it had assumed, never mind how, a distinct mineral banding, the layers varying in thickness from a small fraction of an inch upwards. Would this structure survive the mechanical deformation? I can give an answer which will at any rate carry us a certain way. I can prove that subsequent pressure has frequently failed to obliterate an earlier banded structure. In such a district as the Alps we commonly find banded gneisses and banded schists, which have been exposed to great pressure. Exactly as in the former case, the new divisional planes are indicated by a coating of films of mica, by which the fissility of the rock in this direction is increased. The mass has assumed a cleavage-foliation. I give it this name because it is due to the same cause as ordinary cleavage, but is accompanied by mineral change along the planes of division; while I term the older structure stratification-foliation, because so frequently, if it has not been determined by a stratification of the original constituents, it is at any rate a most extraordinary imitation of such an arrangement. In many cases the new structure is parallel with the old, but in others, as in the "strain-slip" cleavage of a phyllite, the newer can be seen distinctly cutting across the older mineral banding. As an example, take a rock mainly consisting of quartz and mica. Sometimes there has been a certain amount of crushing of the constituents, followed by a re-crystallization of the quartz and the formation of a pale-coloured mica. Sometimes, when the direction of the disturbance has been at right angles to the stratification-foliation, the latter is made wavy, and the mica-flakes are twisted round at right angles to their original position. Sometimes there has been a dragging or shearing of the mass, so that a considerable amount of mica has been re-crystallized along the new planes of division. To put it briefly, I assert, as the result of examining numbers of specimens, that though in certain cases the new structure is dominant, a practised eye seldom fails to detect traces of the older foliation, while in a large number of instances it is still as definite as the stripe in a slate.

We have got, then, thus far, that pressure acting on rocks previously crystallized can produce a foliation; but when it has acted in Palæozoic or later times, the resulting structures can be identified, and these, as a rule, are distinguishable from those of the most ancient foliated rocks, while at present we have found no proof that pressure alone can produce any conspicuous mineral banding. I am aware that this statement will be disputed, but I venture to plead, as one excuse for my temerity, that probably few persons in Great Britain have seen more of crystalline rocks, both in the field and with the microscope, than myself. So, while I do not deny the possibility of a well-banded rock being due to pressure alone, I unhesitatingly affirm that this at present is a mere hypothesis—an hypothesis, moreover, which is attended by serious difficulties. For, if we concede that, in the case of many rocks originally granular, dynamic metamorphism has produced a mineral banding, this is only on a very small scale: the layers are but a small fraction of an inch thick. No one

could for a moment confuse a sheared granite from the Highlands with a Laurentian gneiss from Canada or with an uninjured Hebridean gneiss. For the former to attain to the condition of the latter, the mass must have been brought to a condition which admitted of great freedom of motion amongst the particles, almost as much, in short, as among those of a molten rock. Clearly, the dynamic metamorphism of Palæozoic or later ages appears to require some supplementary agency. Can we obtain any clue to it?

An explanation of broadly-banded structures was long since suggested, and has recently been urged with additional force, which avoids some of our difficulties. We know that the process of consolidation in a coarsely crystalline rock has often been a slow one; the constituent minerals separate gradually from the magma, of which sometimes so little may remain, that a rock with a true glassy base has been mistaken for one holocrystalline. The residual and still unsolidified magma would admit of a slow flowing of the mass, but there would be so little of it that the crystals already individualized, though altered in position by differential movements, would be affected by strains, and liable to fracture. Such a rock, when finally consolidated, would exhibit many phenomena in common with a rock modified by dynamic metamorphism, but would differ in the greater coarseness of its structure. This may prove to be the correct explanation of the curious foliated and banded gabbros in the Lizard district. That some crystalline rocks must have passed through this stage I am now in a position to affirm, from evidence not yet published.

Let us, however, see whether another line of investigation may not throw some light on our difficulty. I have already mentioned the effect produced by the intrusion of large masses of igneous rocks upon other rocks. These may be either igneous rocks already solidified, or sedimentary rocks. The former may be passed over, as they will not materially help us. In regard to the latter, the results of contact-metamorphism, as it is called, are, as we might expect, very various. Speaking only of the more extreme, we find that sandstones are converted into quartzites; limestones become coarsely crystalline, all traces of organisms disappearing, and crystalline silicates being formed. In clayey rocks all signs of the original sediments disappear, crystalline silicates are formed, such as mica (especially brown), garnet, andalusite, and sometimes tourmaline; felspar, however, is very rare. Fair-sized grains of quartz appear, either by enlargement of original granules or by independent crystallization of the residual silica. It is further important to notice that, as we approach the surface of the intrusive mass—that is, as we enter upon the region where the highest temperature has been longest maintained—the secondary minerals attain a larger size and are more free from adventitious substances—that is, they have not been obliged as they formed to incorporate pre-existing constituents. The rock, indeed, has not been melted down, but it has attained a condition where a rather free molecular movement became possible, and a new mineral in crystallizing could, as it were, elbow out of the way the more refractory particles. I can, perhaps, best bring home to you the result of contact-metamorphism by showing you what its effects are on a rock similar to that which I exhibited in illustration of the effect of pressure-metamorphism on a distinctly stratified rock. These are, in brief, to consolidate the rock, and while causing some constituents to vanish, to increase greatly the size of all the others. It follows, then, that mineral segregation is promoted by the maintenance for some time of a high temperature, which is almost a truism. I may add to this that, though rocks modified by contact-metamorphism differ from the Archæan schists, we find in them the best imitations of stratification-foliation, and of other structures characteristic of the latter.

One other group of facts requires notice before we proceed to draw our inferences from the preceding. Very commonly, when a stratified mass rests upon considerably older rocks, the lower part of the former is full of fragments of the latter. Let us restrict ourselves to basement beds of the Cambrian and Ordovician—the first two chapters in the stone-book of life. What can we learn from the material of their pages? They tell us that granitoid rocks, crystalline schists of various kinds, as well as quartzites and phyllites, then abounded in the world. The Torridon sandstone of Scotland proves that much of the subjacent Hebridean had even then acquired its present characteristics. The Cambrian rocks of North and South Wales repeat the story, notably near Llynfaelog in Anglesey, where the adjacent gneissoid rocks from which the pebbles were derived, even if once true granites, had assumed their differences before the end of the Cambrian period. By the same time similar changes had affected the crystalline rocks of the Malverns and parts of Shropshire. It would be easy to quote other instances, but these may suffice. I will only add that the frequent abundance of slightly-altered rocks in these conglomerates and grits appears significant. Such rocks seem to have been more widely distributed—less local—than they have been in later periods. Another curious piece of evidence points the same way. In North America, as is well known, there is an ancient group of rocks to which Sir W. Logan gave the name Huronian, because it was most typically developed in the vicinity of Lake Huron. Gradually great confusion arose as to what this term really designated. But now, thanks to our fellow-workers on the other side of the Atlantic, the fogs, gendered in the laboratory, are being dispelled by the light of microscopic research and the fresh air of the field. We now know that the Huronian group in no case consists of very highly-altered rocks, though some of its members are rather more changed than is usual with the British Cambrians, than which they are supposed to be slightly older. Conglomerates are not rare in the Huronian. Some of these consist of granitoid fragments in a quartzose matrix. We cannot doubt that the rock was once a pebbly sandstone. Still the matrix, when examined with the microscope, differs from any Palæozoic sandstone or quartzite that I have yet seen. Among grains of quartz and felspar are scattered numerous flakes of mica, brown or white. The form of these is so regular that I conclude they have been developed, or at least completed, *in situ*. Moreover, the quartz and the felspar no longer retain the distinctly fragmental character usual in a Palæozoic grit, but appear to have received secondary enlargement. A rock of fragmental origin to some extent has simulated or reverted to a truly crystalline structure. In regard to the larger fragments we can affirm that they were once granitoid rock, but in them also we note incipient changes such as the development of quartz and mica from felspar (without any indication of pressure), and there is reason to think that these changes were anterior to the formation of the pebbles.

To sum up the evidence. In the oldest gneissoid rocks we find structures different from those of granite, but bearing some resemblance to, though on a larger scale than, the structures of vein-granites or the surfaces of larger masses when intrusive in sedimentary deposits. We find that pressure alone does not produce structures like these in crystalline rocks, and that when it gives rise to mineral banding this is only on a comparatively minute scale. We find that pressures acting upon ordinary sediments in Palæozoic or later times do not produce more than colourable imitations of crystalline schists. We find that when they act upon the latter the result differs, and is generally distinguishable from stratification-foliation. We see that elevation of temperature obviously facilitates changes, and promotes coarseness of structure. We see also that the rocks in a crystalline series which appear to occupy the highest position seem to be the least metamorphosed, and present the strongest resemblance to stratified rocks. Lastly, we see that mineral change appears to have taken place more readily in the later Archæan times than it ever did afterwards. It seems, then, a legitimate induction that in Archæan times conditions favourable to mineral change and molecular movement—in short, to metamorphism—were general, which in later ages have become rare and local, so that, as a rule, these gneisses and schists represent the foundation-stones of the earth's crust.

On the other side what evidence can be offered? In the first place, any number of vague or rash assertions. So many of these have already come to an untimely end, and I have spent so much time and money in attending their executions, that I do not mean to trouble about any more till its advocates express themselves willing to let the question stand or fall on that issue. Next, the statement of some of the ablest men among the founders of our science, that foliation is more nearly connected with cleavage than with structures suggestive of stratification. In regard to this I have already admitted, in the case of the more coarsely crystalline rocks, what is practically identical with their claim, for they also assert that when the banding was produced, very free movement of the constituents was possible; and in regard to the rest I must ask whether they were speaking of cleavage-foliation or stratification-foliation, which had not then been distinguished, and I know in some instances what the answer will be. The third objection is of a general nature. To

prevent the possibility of misstatement I will give it as a quotation:—"To a geologist (especially one belonging to the school of Lyell) it is equally difficult to conceive that there should be a broad distinction between the metamorphic rocks of Archæan and post-Archæan age respectively, as that the pre-Tertiary volcanic rocks should be altogether different in character from those of Tertiary and recent times." Of course in this statement much depends on the sense attached to the epithet "broad." As an abstract proposition I should admit, as a matter of course, that from similar causes similar consequences would always follow. But in the latter part of the quotation lurks a *petitio principii*. During the periods mentioned volcanic rocks appear, as we should expect, to have been ejected from beneath the earth's crust similar in composition and condition, and to have solidified with identical environment. Hence the results, allowing for secondary changes, should still be similar. But to assume that the environment of a rock in early Archæan times was identical with that of similar material at a much later period is to beg the whole question. My creed, also, is the uniformitarian; but this does not bind me to follow a formula into a position which is untenable. Other studies with which I have some familiarity have warned me that a blind orthodoxy is one of the best guides to heresy. "The weakness and the logical defect of uniformitarianism"—these are Prof. Huxley's words—"is a refusal, or at least a reluctance, to look beyond the 'present order of things,' and the being content for all time to regard the oldest fossiliferous rocks as the *Ultima Thule* of our science." Now, speaking for myself, I see no evidence since the time of these rocks, as at present known, of any very material difference in the condition of things on the earth's surface. The relations of sea and land, the climate of regions, have been altered; but because I decline to revel in extemporized catastrophes, and because I believe that in Nature order has prevailed and law has ruled, am I therefore to stop my inquiries where life is no longer found, and we seem approaching the firstfruits of the creative power? Because palæontology is, perforce, silent; because the geologist can only say, "I know no more," must I close my ear to those who would turn the light of other sciences upon the dark places of our own, and meet their reasoning with the exclamation, "This is not written in the book of uniformity"? To do this would be to imitate the silversmiths of old, and silence the teacher by the cry, "Great is Diana of the Ephesians."

What, then, does the physicist tell us was the initial condition of this globe? I will not go into the vexed question of geological time, though as a geologist I must say that we have reason to complain of Sir W. Thomson. Years ago he reduced our credit at the bank of time to a hundred millions of years. We grumbled, but submitted, and endeavoured to diminish our drafts. Now he has suddenly put up the shutters, and declared a dividend of less than four shillings in the pound. I trust some aggrieved shareholder will prosecute the manager. However, as a *cause célèbre* is too long a business for the end of an evening, I will merely say that, while personally I see little hope of arriving at a chronological scale for the age of this earth, I do not believe in its eternity. What, then, does the physicist tell us must have been in the beginning? I pass by those earliest ages, when, as "Ilion, like a mist, rose into towers," so from the glowing cloud the great globe was formed. I pass on to a condition more readily apprehended by our faculties—the time, the *consistentior status* of Leibnitz, when the molten globe had crusted over, and its present history began. Rigid uniformitarian though you may be, you cannot deny that when the very surface of the ground was at a temperature of at least 1000° F., there was no rain, save of glowing ashes—no river, save of molten fire. Now is ending a long history with which the uniformitarian must not reckon—of a time when many compounds now existing were not dissolved but dissociated, for combination under that environment was impossible. Yet there was still law and still order—nay, the present law and order may be said even then to have had a potential existence—nevertheless to the uniformitarian gnome, had such there been, every new combination of elements would have been a new shock to his faith, a new miracle in the earth's history. But at the times mentioned above, though oxygen and hydrogen could combine, water could not yet rest upon the ruddy crust of the globe. What does that mean? This, that assuming the water of the ocean equivalent to a spherical shell of the earth's radius and two miles thick, the very lava-stream would consolidate under a pressure of about 310 atmospheres, equivalent to nearly 4000 feet of average rock.[1] But on the practical bearing of this consideration I will not dwell. Let us pass on to a time which, according to Sir W. Thomson, would rather quickly arrive, when the surface of the crust had cooled by radiation to its present temperature. Let us, merely for illustration, take a surface temperature of 50° F. (nearly that of London), and assume that the present rise of crust temperature is 1° F. for every 50 feet of descent, which is rather too rapid. If so, 212° F. is reached at 8100 feet, and 250° F. at 10,000 feet. Though the latter temperature is far from high, yet we should expect that under such a pressure chemical changes would occur with much more facility than at the surface. But many Palæozoic or even later rock masses can now be examined which at a former period of their history have been buried beneath at least 10,000 feet of sediment; yet the alteration of their constituents has been small: only the more unstable minerals have been somewhat modified, the more refractory are unaffected. But for a limited period after the *consistentior status*, the increase of crust temperature in descending would be far more rapid; when one-twenty-fifth of the whole period from that epoch to the present had elapsed, and this is no inconsiderable fraction, the rate of increase would be 1° for every 10 feet of descent. Suppose, for the sake of comparison, the surface temperature as before, the boiling-point of water would be reached at 1620 feet, and at 10,000 feet, instead of a temperature of 250° F., we should have one of 1050° F. But at the latter temperature many rock masses would not be perfectly solid.[2] According to Sorby, the steam cavities in the Ponza trachyte must have formed, and thus the rock have been still plastic at so low a temperature as 680° F. At this period, then, the end of the fourth year of the geological century, whatever be its units, structural changes in igneous and chemical changes in sedimentary rocks must have occurred more readily than in any much later period in the world's history. A temperature of 2000° F., sufficient to melt silver—more than sufficient to melt many lavas—would have been reached at a depth of about 4 miles. It would now be necessary to descend for at least 20 miles in order to arrive at this zone. It, during the ninety-six years of the century, has been changing its position in the earth's crust, more slowly as time went on, from the one level to the other.

There is another consideration, too complicated for full discussion, too uncertain, perhaps, in its numerical results to be more than mentioned at present, which, however, seems to me important. It is this, that in very early times, as shown by Prof. Darwin and Mr. Davison, the zone in the earth's crust, at which lateral thrust ceases and tension begins, must have been situated much nearer to the surface than at present. If now, at the end of the century, it is at the depth of 5 miles, it was, at the end of the fourth year, at a depth of only 1 mile. Then, a mass of rock, 10,000 feet below the surface, would be nearly a mile deep in the zone of tension. Possibly this may explain the mineral banding of much of our older granitoid rock, already mentioned, and the coincidence of foliation with what appears to be stratification in the later Archæan schists, as well as the certainly common coincidence of microfoliation with bedding in the oldest indubitable sediments.

Pressure, no doubt, has always been a most important factor in the metamorphism of rocks; but there is, I think, at present some danger in over-estimating this, and representing a partial statement of truth as the whole truth. Geology, like many human beings, suffered from convulsions in its infancy; now, in its later years, I apprehend an attack of pressure on the brain.

The first deposits on the solidified crust of the earth would obviously be igneous. As water condensed, denudation would begin, and stratified deposits, mechanical and chemical, become possible, in addition to detrital volcanic material. But at that time the crust itself, and even stratified deposits, would often be kept for a considerable period at a temperature similar to that afterwards produced by the invasion of an intrusive mass. Thus not only rocks of igneous origin (including volcanic ashes) would predominate in the lowest foundation-stones, but also secondary changes would occur more readily, and even the sediments or precipitates should be greatly metamorphosed. Strains set up by a falling temperature would produce, in masses still plastic, banded structures, which, under the peculiar circumstances,

[1] If we take the specific gravity of water as unity, and that of mean rock as 2·7, the pressure would be = 3911·1 feet of rock.

[2] The lowest temperature, which, so far as I know, has been observed in lava (basic) while still plastic, is 1228° F.

might occur in rocks now coarsely crystalline. As time went on, true sediments would predominate over extravasated materials, and these would be less and less affected by chemical changes, and would more and more retain their original character. Thus we should expect that as we retraced the earth's course through "the corridor of time," we should arrive at rocks which, though crystalline in structure, were evidently in great part sedimentary in origin, and should beyond them find rocks of more coarsely-crystalline texture and more dubious character, which, however, probably were in part of a like origin; and should at last reach coarsely-crystalline rocks, in which, while occasional sediments would be possible, the majority were originally igneous, though modified at a very early period of their history. This corresponds with what we find in Nature, when we apply, cautiously and tentatively, the principles of interpretation which guide us in stratigraphical geology.

I have stated as briefly as possible what I believe to be facts. I have endeavoured to treat these in accordance with the principles of inductive reasoning. I have deliberately abstained from invoking the aid of "deluges of water, floods of fire, boiling oceans, caustic rains, or acid-laden atmospheres," not because I hold it impossible that these can have occurred, but because I think this epoch in the earth's history so remote and so unlike those which followed, that it is wiser to pass it by for the present. But unless we deny that any rocks formed anterior to or coæval with the first beginning of life on the globe can be preserved to the present time, or, at least, be capable of identification (an assumption which seems to me gratuitous and unphilosophical) then I do not see how we can avoid the conclusion to which we are led by a study of the foundation-stones of the earth's crust—namely, that these were formed under conditions and modified by environments which, during later geological epochs, must have been of very exceptional occurrence. If, then, this conclusion accords with the results at which students of chemistry and students of physics have independently arrived, I do not think that we are justified in refusing to accept them, because they lack the attractive brilliancy of this or that hypothesis, or do not accord with the words in which a principle, sound in its essence, has been formulated. It is true in science, as in a yet more sacred thing, that "the letter killeth, the spirit giveth life."

SYSTEMATIC RELATIONS OF PLATYPSYLLUS AS DETERMINED BY THE LARVA.

PROF. C. V. RILEY, in a paper read at a recent meeting of the National Academy of Science (U.S.A.), drew attention to the unique character of *Platypsyllus castoris*, a parasite of the beaver; and gave an epitome of the literature on the subject, showing how the insect had puzzled systematists, and had been placed by high authority among the Coleoptera and the Mallophaga, and made the type even of a new order. He showed the value, as at once settling the question of its true position, of a knowledge of the adolescent states. He had had since November 1886 some 14 specimens of the larva, obtained from a beaver near West Point, Nebraska, and had recently been led to study his material at the instance of Dr. Geo. H. Horn, of Philadelphia, who at a recent meeting of the Entomological Society of Washington announced the discovery of the larva by one of his correspondents the present spring, and will publish a full description of it. Prof. Riley indicated the undoubted Coleopterological characteristics of the insect in the imago state, laying stress on the large scutellum and five-jointed tarsi, which at once remove it from the Mallophaga, none of which possess these characters. He also showed that the larva fully corroborates its Coleopterological position, and that its general structure, and particularly the trophi, anal cerci, and pseudopod, confirm its Clavicorn affinities. He showed that the atrophied mandibles in the imago really existed as described by Le Conte, and that even in the larva they were feeble and of doubtful service in mastication. He mentioned, as confirmatory of these conclusions, the finding by one of his agents, Mr. A. Koebele, of Leptinillus (the Coleopterological nature of which no one has doubted, and the nearest ally to Platypsyllus), associated with Platypsyllus upon beaver-skins from Alaska; also the parasitism of Leptinus upon mice. He paid a high compliment to the judgment and deep knowledge of the late Dr. Le Conte, whose work on the imago deserves the highest praise, and whose conclusions were thus vindicated. "Platypsyllus therefore," he concluded, "is a good Coleopteron, and in all the characters in which it so strongly approaches the Mallophaga it offers merely an illustration of modification due to food, habit, and environment. In this particular it is, however, of very great interest as one of the most striking illustrations we have of variation in similar lines through the influence of purely external or dynamical conditions, and where genetic connection and heredity play no part whatever. It is at the same time interesting because of its synthetic characteristics, being evidently an ancient type, from which we get a very good idea of the connection in the past of some of the present well-defined orders of insects."

SCIENTIFIC SERIALS.

Atti della R. Accademia dei Lincei, July and August 1888.—In both of these numbers G. Vicentini and D. Omodei continue their important inquiries on the thermic expansion of certain binary alloys in the liquid state. So far they have arrived at the following general conclusions: (1) the variation of volume accompanying liquid metallic mixtures is extremely slight; (2) no relation can be established between the variations of volume that accompany the formation of alloys in the solid and liquid states; (3) the variation of density at the moment of solidification is in general less than would be the case were the constituent metals to preserve in the alloys the value that they possess in the isolated state; (4) the binary alloys of lead and tin, of tin and bismuth, and of tin and cadmium, possess in the state of perfect fusion an expansion equal to that resulting from the sum of the expansions of the associated metals; (5) the alloy of Bi_2Pb possesses a coefficient of expansion far greater than the sum of the expansions of the constituent metals. These experiments, which conclude for the present with a preliminary study of the antimony and zinc alloys, have been carried out at the physical laboratory of the University of Cagliari, Sardinia.

Rivista Scientifico-Industriale, October.—Experiments made with Crookes's radiometer, by Prof. Pietro Lancetta. The experiments here described have been undertaken chiefly for the purpose of making a synthesis of certain phenomena which are more easily produced by this apparatus than by any other means. It is also shown that the radiometer may in some cases be more advantageously employed than the ordinary thermometer, especially in testing certain laws regarding latent and luminous heat, Crookes's instrument being sensible both to the dark and luminous wave of the solar rays. The results of the experiments show generally that in a homogeneous medium the radiation of the thermo-luminous wave is propagated in a straight line; that the luminous wave is propagated *in vacuo*; that the intensity of the thermo-luminous wave is in inverse ratio to the square of the distance; that the evaporation of fluids as well as the rarefaction of gaseous bodies is accompanied by a lowering of the temperature, while the condensation of gas develops heat.

Journal of the Russian Chemical and Physical Society, vol. xx. fasc. 6.—On the speed and the products of decomposition of the chlorate and chlorite of lithium, by A. Potilitzin, being the second part of an inquiry into the properties of galloid compounds. The decomposition of the two above-mentioned salts, as well as of the bromate of barium, is best explained according to the law of unstable equilibrium indicated by the author in his former works, and which he sums up as follows: in each chemical reaction the equilibrium of the system depends upon the values of their atomic weights, their masses, and their stock of potential energy.—On the relation between the rotatory power and the refraction of organic compounds, by J. Kanonnikoff, first part.—On the action of organic iodides on natrium-nitro-ethane, by N. Sokoloff.—Obituary notice of Prof. Wroblewski, by S. Lamansky.—The total eclipse of the sun of August 19, 1887, by N. Egoroff; and on the results of meteorological observations during the same eclipse, by N. Hesehus.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 31.—"On the Effect of Occluded Gases on the Thermo-electric Properties of Bodies, and on their Resistances; also on the Thermo-electric and other Properties of Graphite and Carbon." By James Monckman, D.Sc. Communicated by Prof. J. J. Thomson, F.R.S.

A piece of platinum wire about 18 inches long was bent in the middle, and one-half protected by being covered with glass tube and made water-tight at the lower end. After annealing the free portion and testing until perfectly free from all strain effects, it was placed, up to about the middle, in acidulated water, and made the negative pole of a battery, and hydrogen liberated upon it for a few minutes. After being dried it was tested with a small flame at distances 1 cm. along its whole length. The result was a current from free wire towards that part on which hydrogen had been produced, greatest at the junction of the free wire and the saturated wire.

When wires of palladium were used, more powerful effects of the same kind were produced.

Carbon rods were next tried. It was found that when one of these rods was heated and placed against the other, the current was always from cold to hot below 200° C.

They were then used as the electrodes in decomposing dilute sulphuric acid, dried carefully until no current was produced on placing them in contact. On heating either rod and joining them as before, a current was produced from hydrogen to oxygen across the hot junction.

The same effect was obtained by decomposing hydrochloric acid solution.

Resistance.—To get rid of possible error from change of temperature, two wires of equal length and section were used and balanced against each other.

These were placed in water, and a current passed from the one to the other, allowed to remain in the acid a little to cool if necessary, and afterwards removed, dried, and placed in an empty glass vessel surrounded with a considerable quantity of water. There they rested until the temperature became the same as the water. When measured, the resistance of the wire containing the hydrogen was found to have increased about one-thousandth part.

Carbon.—Two thin rods about 2mm. diameter were electroplated at the ends and soldered to insulated copper wires.

When used as the poles of a battery the change of resistance was considerable, but greater on the rod that had been the positive pole. By using a platinum electrode, hydrogen or oxygen was produced at will upon the same rod, the other rod remaining unchanged. It then appeared that oxygen increased the resistance much more than hydrogen, rising in some cases as high as nine times; that when oxygen was liberated twice or thrice in succession the resistance increased each time. This continued increase was probably due to chemical changes produced by the active oxygen. Hydrogen gave an increase of resistance, not continuing beyond a certain point, and not becoming greater on repeated charging with the gas.

Generally also the effect of the hydrogen was temporary, disappearing, wholly in some cases, partially in others, when short circuited.

Superposition of Polarization.—Part of the change in the carbon is evidently produced by the mechanical action of the gases evolved, and by the chemical action of the oxygen; both of these will, however, produce permanent changes. That only part of the action is to be explained in this way is shown by the previous experiments. It is, however, further demonstrated by using two carbon rods in decomposing acidulated water; after passing the current for one minute, reverse it for one-tenth of a second and immediately join up to a galvanometer. A short but violent deflection appears for the latter contact, gradually falling to zero and passing to the other side, where it remains for a considerable time, though with much decreased quantity.

The same thing was obtained with platinum electrodes. The second contact must be very short, or the former polarization disappears.

Thermo-electric and other Properties of Graphite and Carbon.—In making the previous experiments, I had occasion to place the heated end of one carbon rod in contact with the cold end of another. The temperature of the hot end was varied from 30° C. to a red heat, whilst the cold end was kept at about 17° C.

Currents of electricity were of course produced. When the temperature of the hotter rod was raised but slightly, the current was from cold to hot through the point of contact, but when it was raised to a red heat the current passed from hot to cold.

I was led to expect that the line of carbon in a thermo-electric diagram, in which the area of the space between the lines is proportional to the electromotive force, would show a bend of some kind, and as no researches were known showing such a bend, it appeared desirable to test it carefully.

Near one end of a carbon rod a hole, about 5 mm. in diameter, was drilled, and into this the end of a platinum wire was inserted and fixed by being wedged with a piece of rod carbon. The whole was thoroughly covered with Indian ink, which, when dry, was again covered with clay. The carbon rod was insulated from the platinum wires, and they from each other by thin sheet asbestos and mica, by which means it was insulated from the vessel in which it was placed, and luted with clay to prevent access of air. From several series of experiments a thermo-electric line was calculated, and found to rise from 0° to 250°, beyond which it descended at the same rate.

Other Changes in the Properties of the Body at the same Temperature.

This change in the thermo-electric power of carbon is accompanied by other changes. The resistance, the expansion, and the specific heat all appear to undergo a corresponding alteration, as the following summary of results shows:—

	Below 250° C.	Above 250° C.
A. Effect of contact of hot and cold carbon.	Current from cold to hot.	Current from hot to cold.
B. Thermo-electric line	Rises.	Falls.
C. Rate of decrease of resistance per degree per ohm	Diminishes.	Increases.
D. The rate of increase of the coefficient of expansion	Increases.	Decreases.
E. Rate of increase of the specific heat	Fairly regular.	Falls to half.

Geological Society.—November 7.—Dr. W. T. Blanford, F.R.S., President, in the chair.—The following communications were read:—The Permian rocks of the Leicestershire coal-field, by Horace T. Brown. According to Mr. Brown, the Permian rocks of the Leicestershire coal-field belong to the same area of deposition as those of Warwickshire and South Staffordshire, all having formed part of the detrital deposits of the Permian lake which extended northwards from Warwickshire and Worcestershire, and which had the Pennine chain on its eastern margin. He pointed out the dissimilar nature of these deposits to those of the eastern side of the Pennine chain from Nottingham to the coast of Durham. There were proofs of the existence of a land barrier, owing to the uprising of the Carboniferous, between the district round Nottingham and the Leicestershire coal-field. The most northerly exposure of the Leicestershire Permians is thirteen miles south-west of those of South Notts. He indicated the probable course of the old coast-line of the western Permian lake. Denudation had bared some of the older Palæozoics of their overlying Coal-measures, and it is the rearranged talus from the harder portions of these older rocks which now forms the brecciated bands in the Leicestershire Permians. The reading of the paper was followed by a discussion, in which the President, Prof. Bonney, Mr. Whitaker, Prof. Blake, and Mr. Topley took part.—On the superficial geology of the central plateau of North-Western Canada, by J. B. Tyrrell, Field Geologist of the Geological and Natural History Survey of Canada. The drift-covered prairie extends from the west side of the Lake of the Woods to the region at the foot of the Rocky Mountains, rising from a height of 800 feet on the east to 4500 feet on the west, the gentle slope being broken by two sharp inclines known as the Pembina Escarpment and the Missouri Coteau, giving rise to the First, Second, and Third Praire Steppes. The author described the older rocks of this region, referring especially to his subdivision of the Laramie formation into an Edmonton series of Cretaceous age, and a Pascapoo series forming the base of the Eocene, and then discussed the superficial deposits in the following order: (1) *Preglacial gravels;* occurring along the foot of the Rocky Mountains, composed of waterworn quartzite pebbles, similar to those now forming, and, like them, produced by streams flowing from the mountains; (2) *Boulder-clay* or *Till;* (3) *Interglacial deposits* of stratified material; (4) *Moraines;* (5) The *Kames* or *Åsar*, generally occurring at the bottoms of wide valleys; (6) *Stratified deposits* and beach-ridges which have been formed at the bottoms and along the margins of fresh-water lakes lying along the foot of the ice-sheet; (7) *Old Drainage-channels.* Some remarks on this paper were made by the President, Dr. Hinde, Mr. Whitaker, Mr. Topley, and Mr. Marr.

PARIS.

Academy of Sciences, November 12.—M. Janssen in the chair.—On the cultivation of the square-eared variety of wheat in 1887 and 1888, by MM. E. Porion and P. P. Dehérain. The results of two years' experience in various parts of France show that this variety of red wheat yields under favourable conditions crops which till lately would have been thought fabulous. It succeeds best on well-drained heavy clay soils in the central and northern provinces, and if well manured and sown in regular furrows gives splendid returns; it also shows more power of resisting the destructive action of wind and rain than any other kind.—On the nature of milk, by M. A. Béchamp. This is a reply to the question, Does milk contain any anatomical elements of the system, and if so, do the lacteous globules represent any of these elements? The author's studies lead to the conclusion that milk is not an emulsion; that the lacteous globules are real adipose vesicles in a free state, and that cows' milk contains, besides caseine, other albuminoid substances, not in a free state, but combined in solution with alkalies.—Calculation of the tensions of sundry vapours, by M. Ch. Antoine. Here the general formula $\log p = A\left(D - \frac{1000}{\theta}\right)$ is applied to a number of vapours such as benzene, chloroform, alcohol, carbon chloride, ether, acetone, and carbonic acid, and the comparative results are given for the five temperatures that served as the base for the calculation of Regnault's new formula. The final formulas thus obtained, which had never been worked out by Regnault, must henceforth be adopted in studying the properties of the vapour of acetone.—A new method of improving the capacity of very long telegraphic lines, by M. Fernand Godfroy. This method consists in establishing at each extremity of the line a connection with earth, having a coefficient of self-induction powerful enough, if not to compensate the usual waste, at least greatly to diminish it by the inverse effects which the self-induction tends to produce. The method has already been tried with marked success, on several underground lines, amongst others that between the Paris central station and Angoulême, a distance of 300 miles. Here it was found possible to signal at the rate of twenty words per minute with an *ordinary* Morse apparatus, without any intermediate or local translator, and utilizing one direction only of the current.—On the silicated combinations of glucine, by MM. P. Hautefeuille and A. Perrey. The elements of a leucite or volcanic schorl with aluminia or glucine base ($4SiO_2,Al_2O_3,KO$, or $4SiO_2,Gl_2O_3,KO$), heated between 600° and 800° C. with an excess of neutral vanadate of potassa, are rapidly mineralized. But the nature of the resulting crystals varies in the course of the same operation according as the mineralizing agent yields to the product by which an increasing portion of its alkali is crystallized. Thus this product is homogeneous only under exceptional conditions, and as a rule is a mixture of several chemical species, whose separation is here studied.—Presence of glycolic acid and of normal propylenedicarbonic acid in the grease of sheep's wool, by MM. A. and F. Buisne. In the process of analyzing sheep-washings, the authors have succeeded in isolating these two acids, which are here described. The latter, with formula $COOH—CH_2—CH_2—CH_2—COOH$, is shown to be a higher homologue of succinic acid.—On the Hersiliidæ, a new family of parasitic Copepods, by M. Eugène Canu. Thanks to his discovery at Wimereux of two new genera closely allied to the Hersilia, and parasites of various invertebrates, the author has come to the conclusion that the Hersilia should constitute a new family as distinct from the Siphonostoms as they are from the Peltidians. A full anatomical description is given of this family of Hersiliidæ.—On a new geological map of France, by MM. Jacquot and Michel Lévy. This map, which is on the scale of 1 : 1,000,000, will be issued by the French Geological Service before the close of the year, and will embody the latest researches, including the unpublished reports for 1884–86.—M. du Chatellier has a note on the continued subsidence of the Finistère coast, Brittany; and M. V. Galtier describes some fresh experiments tending to show the efficacy of intra-venous injections of the virus of rabies as a prophylactic against the bite of mad dogs.

Astronomical Society, November 3.—M. C. Flammarion, President, in the chair.—M. Riccò sent a description of a sun-spot observed from November 12 to 25, 1882. This spot, the largest ever observed, had an area over fifty times that of a great circle of the earth. It exhibited rose-coloured veils in some parts, and the nuclei were crossed by large yellow arcs.—M. Gaudibert sent a drawing of Eratosthenes, showing twelve hills within the ring, and a multitude of small craters on the east.—M. Blot, of Clermont (Oise), sent an elementary demonstration of the formula $v^2 = \mu\left(\frac{2}{R} - \frac{1}{a}\right)$, which gives the velocity of a planet in terms of the major axis and of the radius-vector.—Observations of meteors, by M. de Alcantara Penya at Majorca, on June 23, at 7.20 p.m.; by Baroness Ottenfels in the Gulf of Juan, on July 17, at 9 p.m.; by M. Henrionnet at Troyes, on September 9, at 9.30 p.m.—Observations of sun-spots, by MM. Bruguière, Henrionnet, and Loiseau; and of Sawerthal's comet, by MM. Guillaume and Kropp.—M. Guiot, of Soissons, saw the companion to Sirius with a 3¾-inch refractor, and observed Vesta with the naked eye from September 5 to 20.—M. Ferret photographed the moon with a 3⅝-inch refractor.—M. Duprat sent an observation of the lunar eclipse of July 23 made at Constantine.—M. Lihou observed an occultation of a seventh magnitude star by Jupiter.—M. Foray observed Venus on the day of its conjunction, with a 4-inch refractor.—The Sociétés Scientifiques Flammarion, of Marseilles, Argentan, Bruxelles, Jaën, and Bogota, were elected Corresponding Societies.

THURSDAY, NOVEMBER 29, 1888.

HAUPTMANN ON HARMONY AND METRE.

The Nature of Harmony and Metre. By Moritz Hauptmann. Translated and Edited by W. E. Heathcote, M.A. (London: Swan Sonnenschein and Co., 1888.)

THE author of this singular book was a noted man in the German musical world. He was not only an eminent violinist (pupil and intimate friend of Spohr), but a composer of merit, and, what is more to our purpose here, a great authority on the theory of music and the laws of composition. In 1842 he was appointed, on Mendelssohn's recommendation, Cantor and Musik-Director of the celebrated Thomas-Schule at Leipzig, and Professor of Counterpoint and Composition at the new Conservatorium in that city, filling these posts till his death in 1868. He was undoubtedly the foremost teacher in Europe, and his legion of pupils comprised many who afterwards became musicians of great eminence, including F. David, Curschmann, Burgmüller, the Baches, Joachim, von Bülow, Mr. Cowen, and Sir Arthur Sullivan. He was, moreover, a highly educated man and a Doctor of Philosophy. Hence any writings on music by him could not fail to command attention. His best-known work is a series of letters to his intimate friend, Hauser, the Director of the Conservatoire at Munich, full of spirit, admirable criticism, and deep musical knowledge.

Hauptmann's scientific turn of mind led him to study earnestly the problem which has occupied so many thinkers ever since music has had any consistent form—namely, to discover how the structure which, for some reason or other, seemed most appropriate for it, could be accounted for and explained on philosophical principles. The Greeks talked vaguely of the music of the spheres, and learned men of later days referred it to arithmetical proportions; both with as much reason as modern English musicians join in the *ignis-fatuus* hunt after "natural systems of harmony." Hauptmann sought the explanation in the depths of German metaphysics, and having satisfied his own mind on the matter, he brought out, in 1853, an elaborate volume which he called "Die Natur der Harmonik und der Metrik, zur Theorie der Musik," of which the book now before us is an English version. It appears by a part of the original preface (omitted by the present translator) that he had already introduced the system into his "musikalisch-theoretischen Cursus," and there is no doubt it attracted considerable attention in Germany. A second edition of the book was published in 1873.

But in the meantime the matter had assumed a new shape, through the labours of another German philosopher, Helmholtz. He had the advantage over Hauptmann of a large practice in experimental physics; hence it occurred to him to attack the problem on the physical side, and the result was the well-known epoch-making work, published in 1863, "Die Lehre von den Tonempfindungen als physiologische Grundlage für die Theorie der Musik." He investigated, far more thoroughly than anyone had done before, the physical properties of musical sounds, and their physiological effects on the ear. He showed, with the aid of the facts thus obtained, that the structure of music generally in use was due partly to the nature of the sounds of which it was composed, and partly to artificial considerations which had presented themselves to musical composers on æsthetic and artistic grounds. This swept away the necessity for any abstruse metaphysical speculations; and we strongly suspect that if Hauptmann had waited till Helmholtz's discoveries had been made known, the present treatise would never have appeared.

It is a question, under these circumstances, how far it was worth while to reproduce the book in English; however, here it is; and anyone interested in musical metaphysics, or metaphysical music, and who is unable to read the original, may puzzle over it to his heart's content. It is a handsome volume, and the translation is (so far as we have been able to compare it) carefully and intelligently done. Some of the language may seem uncouth, and much of it obscure, but this is inevitable from the nature of the original, the rendering of which must often have been a tough job. The translator has prefixed an introductory essay, and there is an appendix, entitled "A Short Analysis of Hauptmann's Treatise," which, as we do not find it in the original, we presume is the translator's also, though he does not say so.

The main feature of the work is the application, to musical structure, of the philosophy of Hegel. It would be useless here to attempt to discuss this elaborate subject, or even to describe it. All we can do is to insert a few extracts to give an idea of what sort of thing a person must expect who would take up the work.

As a general point of departure, the translator tells us that—

"The fundamental idea of the philosophy is that every notion—as key, scale, seventh chord, resolution, and so on—is made up after this fashion, *i.e.* that it possesses three elements, involving an antithesis and a reconcilement, and that one of the three elements is the root from which the other two, and so the whole construction, spring. This, Hauptmann regards as self-evident, and it is the basis of Hegelian metaphysics."

The author then says:—

"For the first step it will only be requisite to acquire an inward conception of the notion of the formative process in its wholeness, in the unity of its three elements with which we become acquainted in their first utterance, as the intervals of the octave, fifth, and third. This notion is and remains everywhere the same, in every formation and transformation. It is the notion that something, which at first subsists for intuition in immediate totality (octave), parts from itself into its own opposite (fifth), and that then this opposite is in its turn abolished to let the whole be produced again as one with its opposite (triad), as a whole correlated in itself. Going in the universal sense of this notion, we shall soon be obliged to grant that it no less than comprehends in itself the elements of all knowing, and that anything further for knowledge is not conceivable (*dass ein Weiteres für die Erkenntniss nicht mehr denkbar ist*)."

Sound is defined as

"the coming to be of the being which subsists absolutely during rest, and which is alternately abolished and restored. Not being in self, or dead persistence in rest, nor yet being out of self (*ausser-sich-seyn*) in the motion, is sounding, but coming to self (*zu-sich-kommen*)."

The octave is

"the expression for the notion of identity, unity, or equality with self."

The fifth

"contains acoustically the determination that something is divided within itself, and thereby the notion of duality and inner opposition (*sich selbst Entgegengesetztes*)."

The third contains

"the notion of identification of opposites; of duality as unity."

Of the scheme of a major key, as derived from triad construction, it is said :—

"The organic property of a membered whole can never be represented exhaustively, either by symbols and numbers or by words; it can only be spiritually indicated to intellectual feeling, *i.e.* reason, that meets it half-way. . . . . Now, because this notion has to unite both union and separation, it can only be fulfilled in endlessly continued passage into contrary and comprehension of all opposites. Thus it must be conceived as an infinite process, and consequently as the notion of eternal becoming, living or being real. This is Nature, who, produced as duality from the prime unity (*Ureinheit als Zweiheit hervorgegangen*), and busied continually in making her opposites be absorbed into one another, is live being itself and reality."

This is the sort of way in which harmony is treated; and the same system is adopted in the latter part of the book in regard to metre and rhythm. Most elaborate explanations, illustrated with tables and diagrams, are given of all varieties of time, rhythm, and accent, and they are all etherealized in the same transcendental style. For example, in regard to four-timed metre, we are told that—

"It is this inner reconcilement of separation in unity and unity in separation, the completed negation of every negativing excluding element, that speaks to us here in metrical determination as the essence of the triad, but in combinations of notes as the perfection of harmony; and generally in any guise of phenomenon as the perfected notion of determinate reality."

But we must, in justice to the book, explain that it is not entirely given up to Hegel. The translator properly remarks that, independently of the theory involved, it contains an account, written by a skilful musician and experienced teacher, of harmony and metre, in which the received rules are explained on general principles, while upon particular points new and unexpected light is frequently cast. This is true, for, though Hauptmann loved Hegel well, he loved music more, and nothing could repress his desire to amplify his explanations upon it. It is quite delightful to find him now and then throwing the metaphysics overboard, and breaking out into intelligible common-sense language on the facts and rules of harmony. One can only regret that this sort of thing is not general instead of exceptional.

We have good precedent for this regret. Hauptmann's book was well known to Helmholtz. He studied it carefully, made himself master of all its intricacies, and commented on many of his predecessor's statements and opinions with much respect. Yet what judgment did he pass upon Hauptmann's work as a whole? We will give the passage in the original, as it is really a most true and effective criticism. He says (original edition, p. 427) :—

"Ich kann mich nur dem Bedauern anschliessen, welches C. E. Naumann ausgedrückt hat, dass so viele feine musikalische Anschauungen, welche dieses Werk enthält, unnöthiger Weise hinter der abstrusen Terminologie der Hegel'schen Dialectik versteckt und deshalb einem grösseren Leserkreise ganz unzugänglich sind."

It is, indeed, a great pity that so much excellent musical matter, so many "refined musical views," as this work contains, should be hidden in such an atmosphere of impenetrable transcendental fog, and thus rendered inappreciable by any large circle of readers.

There is another reason which adds seriously to the difficulty of understanding these portions—that is, the use of a complicated system of alphabetical letters in varied types to express musical notes, chords, and passages, instead of the ordinary musical notation. The latter conveys its idea at a single glance; the former requires mental labour which is most wearisome. It is true the author explains that he wants in some cases greater accuracy than the ordinary notation will give; but this is obtained at a fearful sacrifice of clearness and intelligibility, and surely the object might have been accomplished in some less repulsive manner.

It seems odd that the translator, in his elaborate explanatory introduction, never mentions or notices Helmholtz in any way. One would hardly have expected that in the present day, when the science of music has come to be based chiefly on Helmholtz's investigations, a philosophical essay on the subject could have been penned without some allusion to them. There are many passages where the comparison seems invited; for example, Mr. Heathcote says: "The science of music is concerned more with the form than the materials." This is directly at variance with the work of Helmholtz, who bases all his science on the nature of the materials of music—namely, musical sounds—leaving the form to develop itself therefrom. Again, in explaining to us how we are to proceed to learn and follow out the Hegelian system, the translator says :—

"Therefore, when musical sound is said to be unity, we are not to think of it as existing as it does now, and capable of being distinguished into chords, notes, and scales. . . . . Musical pitch, tone, or quality of sound, which depend upon the triad, must not be thought of as existing before the triad exists, and still less as contributing to the formation of the triad."

How different this is from the philosophy of Helmholtz, who demonstrates to us that the triad is a product directly springing out of the physical nature of musical sound!

To sum up, the book is a very remarkable one, the product of a great mind, and of a great authority on the subject it treats of. But we should fear that its interest to English readers will be very limited. The Hegelian portion of it, although, as the translator remarks, it may serve the metaphysician as an application of this peculiar philosophy to a concrete subject, can be of little use to the musician as an explanation of the principles of his art. And as to the technical musical matter, which is really very valuable, the way to render its value appreciable by the public would be to translate it, not merely into English, but into a kind of language with which musicians are familiar, and which ordinary minds would be able to comprehend. W. POLE.

BOTANY OF SOCOTRA.

Botany of Socotra. By Isaac Bayley Balfour, M.D., F.R.S., &c., assisted by other Botanists. Forming Vol. XXXI. of the Transactions of the Royal Society of Edinburgh. (Edinburgh: Grant and Son. London: Williams and Norgate. 1888.)

UNDER the auspices of the Royal Society of London and the British Association for the Advancement of Science, Dr. Bayley Balfour proceeded to Socotra early in 1880, accompanied by Mr. A. Scott, a gardener, and joined at Aden by Lieut. Cockburn, for the purpose of investigating the natural history of the island. Originally it was intended that Colonel Godwin-Austen should lead the Expedition, but circumstances prevented him; and the Committee, through Sir Joseph Hooker, thereupon requested Dr. Balfour—who had recently completed an account of the results of his botanical exploration of the Island of Rodriguez—to undertake the task. He had just been appointed to the Botanical Chair in the University of Glasgow, and the duties connected therewith demanded his presence after the middle of April, therefore the duration of the expedition was necessarily very limited, and the time actually spent on the island was little more than six weeks, ending on March 30. Nevertheless, the botanical collections included specimens of between five and six hundred species of Phanerogams, besides Cryptogams; though, as might be expected from the hasty manner in which the work had to be performed, and the short season during which the plants were collected, many of the specimens were imperfect. The following spring a party of German naturalists visited the island, among them the distinguished African traveller and botanist, Dr. Schweinfurth, to whom Dr. Balfour sent a catalogue of the plants he himself collected, with the gratifying result presently to be explained.

Fortunately the German Expedition entered upon its labours a fortnight later than the time when the British Expedition finished its work. Vegetation was then at a later stage of development; and Dr. Schweinfurth was able to supplement largely Dr. Balfour's botanical collections, especially in the direction of much more complete material. The unselfish devotion to science displayed by Dr. Schweinfurth is eulogized by Dr. Balfour in the following words:—

"With a generosity which is as pleasing as it is rare, he subsequently sent his collections to me in England, in order that the whole flora might be worked out in one. I have already had opportunity to express publicly my lively appreciation of this act of friendship and self-abnegation, and I wish here to put the fact again on record, and to say how much Dr. Schweinfurth's specimens have contributed to the satisfactory working out of the details of the flora. The value of his collection must not be measured either by the number of the species, or by the species he found which we had not gathered. In the excellence of his specimens and their completeness, and the way in which they so frequently supplemented, in flower and fruit characters, deficiencies in ours—therein lay the value of Schweinfurth's plants, and I cannot appraise it too highly."

Dr. Balfour elaborated the joint collections at Kew, and it was announced in NATURE five years ago that he had completed the descriptive part; but delays in connection with the production of the plates, which need not be particularized, we are informed in the preface, prevented the issue of the volume until this year.

It is satisfactory, however, to be able to congratulate Dr. Balfour and the Royal Society of Edinburgh on the quality of the work now first presented to the public in a complete form. Although it may fall considerably short of being an account of all the plants that inhabit the island, it is sufficiently full to be of the utmost value to the student of systematical and geographical botany. Dr. Balfour's 521 pages of letterpress are illustrated by 100 plates, drawn by W. H. and J. N. Fitch, Mrs. Thiselton Dyer, and Miss M. Smith, though mainly by the latter lady. Apart from the descriptive matter, the geographical distribution of the individual species, and the affinities of the flora as a whole, are given in ample detail in the form of an introductory essay, which will rank high among recent contributions to phytogeography. There is also a map on a scale of about $1\frac{1}{4}$ inch to 5 miles, and a brief sketch of the position, physical features, and geology of the island.

Socotra is situated off the north-east corner of Africa, about 500 miles from the entrance to the Red Sea, between 12° and 13° N. lat., and 53° and 54° E. long. Its extreme length from east to west is about 72 miles, its breadth 20; and it is about 140 miles from the nearest point of the African coast, and a little more distant from the Arabian. The surface is mountainous, the interior averaging 1000 feet in altitude, with granite peaks exceeding 4000 feet. The main plateau is of limestone deeply cut into ravines and valleys. In some places the hills rise abruptly from the sea, in others there are intervening sand-plains several miles in width. The climate is cooler and more humid than in the adjacent parts of Africa and Arabia, and in some parts there are perennial streams; but the character of the vegetation generally is that of a dry sterile country.

Out of 575 Phanerogams, or flowering plants, collected, 10, including the date and palmyra palms, orange, cotton, tamarind, and castor-oil, were undoubtedly planted, and many others weeds of wide dispersion; whilst 206 are apparently endemic; and there are 20 endemic genera. Unfortunately, as I think, Dr. Balfour has not deducted the certainly and probably introduced species in his analysis of the composition of the flora, hence his figures representing the percentages of endemic genera and species do not reveal the true facts. Thus he calculates that 36·5 per cent. of the species, and 6·3 per cent. of the genera, are endemic; and these are high percentages, considering the short distance the island is separated from the mainland, and indicate a very ancient flora; but had he eliminated the species in question, these percentages would have stood even higher. On the other hand, it is a mistake to say (Introduction, p. xlix) that the percentage of endemic species is about the same as in Madagascar, where the proportion of endemic genera is double that in the Socotra. The percentage of endemic species in the Madagascar flora is probably at least double that in the Socotran flora, and Mr. Barron, in a paper he recently read before the Linnean Society, estimated the endemic element at 80 per cent. of the species. In British India it is as high as 68 per cent.; in Mexico and Central America combined it reaches 70, and in the whole of Australia 80 per cent.

A comparison of the flora of Socotra with that of the

Bermudas, which are more than three times the distance from the nearest mainland, will give some idea of the differences in the age of the two. The latter contains no endemic genus, and only about half a dozen species, and these are not of a highly differentiated character—one is a portion of a very old flora, and the other a flora of recent derivation. The small flora of Juan Fernandez (which lies about 400 miles from the coast of Chili) contains 21 per cent. of endemic genera and 78 per cent. of endemic species.

The endemic element in Socotra is distributed over fifty-four natural orders, and includes some highly curious types, such as *Cocculus Balfourii*, remarkable for its thick rigid cladodes and often leafless condition; *Thamnosma socotrana*, a member of a Mexican genus; *Dirachma*, a geraniaceous genus of American affinities; *Dendrosicyos*, unique in the Cucurbitaceæ for its arboreous character; *Trichocalyx*, a new genus of the Acanthaceæ; *Cockburnia*, a new genus of the almost exclusively African Selagineæ; and *Cœlocarpus*, a new genus of the Verbenaceæ, having strong American affinities. Of the 136 genera to which the endemic species belong, 98 are only known to be represented by endemic species; and of the 20 endemic genera, 18 are monotypic. The isolated types of American affinities are a repetition of what has also been observed in the fauna and flora of Madagascar.

In summing up, Dr. Balfour finds that the affinities of the flora are essentially tropical African and Asian, the former more pronounced. A former, though very ancient, land connection with Africa he regards as conclusively proved, and the evidence strongly favours the supposition that it was also united with Arabia. With regard to the element of strongest American affinity, its presence is still an unsolvable problem. W. B. H.

THE METALLURGY OF GOLD.

The Metallurgy of Gold; a Practical Treatise on the Metallurgical Treatment of Gold-bearing Ores. By M. Eissler. (London: Crosby Lockwood and Son, 1888.)

THE title suggests that this little volume is a more comprehensive treatise than the author has attempted to write, but it is nevertheless likely to be useful to a large class of readers.

There is a wide-spread belief that, as much of the gold in Nature is found in the "native" or metallic state, its metallurgy must be comparatively simple; and so it would be in nearly all cases if it were not for the fact that the precious metal often occurs in a very fine state of division, or in association with sulphides and tellurides of other metals. Ignorance as to the true nature of such ores has led to their being considered to be "base" or "rebellious," and has entailed much loss and disappointment.

It is asserted, on p. 5, that native gold is never quite pure, being almost invariably alloyed with silver; reference might, however, have been made to the interesting deposit of gold of exceptional purity recently discovered at Mount Morgan, in Australia.

The author points out that "the loss on working gold ores, even with our most modern appliances, is still enormous"; and he gives, among other statistical statements, the results of seven years' working in Colorado, where the average value of the precious metal in the ore, by assay, was £7 18*s.* per ton, while the amount actually extracted was only £3, showing a loss of over 60 per cent. A large section of the work is devoted to the consideration of methods of concentrating the free gold lost during crushing and amalgamating, and the processes for extracting the gold either by amalgamation or by chlorination. The author writes with a practical experience of the processes he describes, but his information is in many cases not up to date.

The illustrations are usually very clear, but in no instance is the scale on which they are drawn given, and there are too few references to the dimensions of the appliances described. The appearance of the illustrations often suggests that they have been borrowed from the trade circulars of the makers of mining machinery. It would surely have been possible to give a more intelligible section of a chlorination works than the one (p. 142) which was suitable enough for its purpose when it originally appeared as an incidental illustration to an Official Report to the United States Government published in 1873; and a far more useful drawing might have been found to accompany the description of the refining of gold by Miller's process than the diagrammatic one which was drawn eighteen years ago by the writer of the present review in order to make the nature of the process clear in an Official Memorandum.

More useful information than is to be found in the twenty-one pages devoted to assaying might easily have been condensed into them, and it is much to be regretted that no attempt has been made to deal with the treatment of tellurides, which are so troublesome to the smelter, and have occasioned so much loss. In a future edition it would also be well to give a description of the process of collecting the precious metals in lead, which plays so important a part in the smelting of complex auriferous ores of lead and copper. Hydraulic mining, also, should find a place. Certain defects of style will no doubt be corrected in a second edition; this will be welcome, for, although the work is hardly in sufficient detail to justify its being called a "practical treatise," it will be useful, especially to men who are engaged in smelting. The author suggests that it contains sufficiently full information for "investors and others interested in gold-mining operations who may wish to gain an intelligent insight into the *modus operandi* at the gold-mines." To them it may be warmly recommended, for, although the element of speculation can hardly be separated from genuine investment in gold-mines, the "adventurers," to use the old name, often deliberately neglect all investigation into the nature of the methods by which they hope to profit. W. C. ROBERTS-AUSTEN.

OUR BOOK SHELF.

Viaggio di L. Fea in Birmania e regioni vicini. II. "Primo saggio sui Ragni Birmani." Del Prof. T. Thorell. (Genova: Tipographia del R. Istituto Sordo-Muti, 1887.)

DR. THORELL deserves our best thanks for having begun a faunistic work on the spiders of Burmah; still greater would have been our gratitude had his minute and exhaustive descriptions been accompanied by figures of the numerous new species recorded. One of the greatest hindrances in the study of exotic araneology is the paucity of such works. The present, however, is not

the first contributed, by Dr. Thorell's labours, for the supply of works on the spider-fauna of exotic regions: witness his extensive work, "Studi sui Ragni Malesi e Papuani," in three volumes, 1877–81, describing and recording over five hundred species of the spiders of that richest of all known exotic regions, the Malay Archipelago. Up to the time of the publication of the present volume, but few Burman spiders were known, the earliest being an Epeirid, described by the late Dr. Stoliczka in 1869. This was followed, in 1878, by two others recorded by Mr. T. Workman, of Belfast; eight more were recorded in 1881 in Dr. Thorell's work above mentioned (on the spiders of the Malay Archipelago); and finally, twenty-two more by M. Eugène Simon in 1884. The total number of species of Burmese Araneidea now known is 163, by far the larger portion being new to science. Dr. Thorell records 145 species, of which 90 are new to science, and 130 new to Burmah. These figures doubtless give a very meagre idea of the spiders of such a rich zoological district as the Burmese Empire. Not to mention its situation in the tropics, Burmah has much in common with the productions of China, Siam, India, and the Malay Archipelago. We may therefore safely hazard a conjecture that the figures given by Dr. Thorell can scarcely represent a twentieth part of the spiders of Burmah. It is to be hoped that since the—still comparatively few—species as yet known have been collated in the present work, an impetus will be given to natural history collectors to add to our knowledge. For the want of figures in Dr. Thorell's work there is some compensation in the concise diagnoses which head each lengthened description. Excepting the introduction, which is in Italian, the work is written in Latin. It is exceedingly well got up, forming a handsome volume of over 400 pages, and is dedicated to the Rev. O. P. Cambridge, General A. W. M. Van Hasselt, and Dr. Ludwig Koch. The greater part of the Burmese spiders described by Dr. Thorell were collected by Signor Leonardo Fea, mostly in Upper (or North) Burmah; and of the rest some were collected in its southern and some in its central districts.

O. P. CAMBRIDGE.

An Introduction to Practical Inorganic Chemistry. By Wm. Jago, F.C.S., F.I.C. (London: Longmans, 1888.)

THIS volume of 72 pages is chiefly taken from the author's "Inorganic Chemistry, Theoretical and Practical," and has been separately issued by request. It is doubtless sufficiently exact for students who are preparing themselves for the "growing number of examinations in which the practical analysis of one or more simple salts is required," and therefore presumably it will serve the end for which it was designed; but it contains many statements that would tend to confuse the genuine student, and give his teacher unnecessary trouble. For instance, on p. 15 it is stated that a "brown ppt. of SnS" is soluble in "SAm_2, re-pptd. by HCl"; and a little lower down that "Arsenic, arsenious compounds . . . Heated in tube—all salts sublime." Both of these statements have so slender a foundation in fact that their direct tendency is to deceive the student. These are mere examples that might be multiplied considerably. Towards the end of the book, tables are given for the "Examination of Mixtures," and wherein they differ from the methods in common use they do not appear to be improvements upon them.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Engineers *versus* "Professors and College Men."

SOME of your readers may recollect that last year (NATURE, vol. xxxv. p. 462) I was led to put the following question to the *Engineer*:—"What is the result of dividing 10 eggs per minute by 2 eggs? Would it, or would it not, be 5 eggs per minute"? To this I have not yet received an answer! It must be very difficult!

I ventured to put the question because the *Engineer* had (in a leading article!) asserted that the result of dividing 3,942,400 foot-pounds per minute, by 33,000 foot-pounds, is 119·4 horse-power. It had actually accused me of ignorance for pointing out the error of such a statement!

But even this remarkable dictum is outstripped in absurdity by some of the *Engineer's* more recent assertions. I quote only a few, any one of which would be sufficient for my present purpose, leaving the vast storehouse to be fully ransacked by other inquirers more curious, and less busy, than myself.

On the 10th of August last the readers of the *Engineer* were treated to the following *ex cathedrâ* pronouncement:—

". . . it is almost impossible to point to anything of value in trade, or manufactures, or engineering which has emanated from the highly-trained Professor or College man."

No comment whatever need be made on this.

A fortnight later, in reviewing a book on the steam-engine, the *Engineer* remarks of Carnot's principle:—

". . . it will soon be understood that with steam this is not true. . . ."

There is nothing in the context to qualify this assertion, rather there is much to intensify and aggravate it. There is manifestly a confusion between temperature and pressure; but it is difficult to find its exact nature; and the only at all analogous case that I can remember is embodied in the indignant outburst of a Celtic student, hard pressed in an "oral," "D'ye mane to till me, Sor, that wather boils at a hundthred degrees in Oireland?"

It might well be thought that we had now gauged the maximum of possible absurdity. But, on September 28, the *Engineer* undertook to enlighten its readers on the subject of Energy; and the effort resulted in some astounding information.

Speaking of "the equation $E = \frac{Mv^2}{2g}$" (a form which will, perhaps, please my friend Prof. Greenhill, though to me it seems to denote merely the product of a mass by a length) our instructor says:—

"The received idea is that, so long as we get E equal to a given number of foot-pounds, it is of no consequence whether we vary v or vary M, . . . but if we introduce the element Time, *which ought not to be left out* [the italics are mine]. . . . The word Energy is unfortunately very vague. . . ." I shall presently recur to this.

October 5 is not without its little novelty. For, as we are gravely informed,

"That much despised faculty, common-sense, has always told engineers that when a given volume of air is passed through a channel or trunk, its pressure will fall as the trunk augments in dimensions."

Even the despised scientific man knows better than that!:—but, true to his convictions, the *Engineer* ignores the conclusions of such mere "Professors and College men" as Bernoulli, Willis, and Sir W. Thomson.

A week later, commenting on some sensible protests (which it prints, in order to refute (?) them) against its marvellous ideas about Energy, the *Engineer* gets back to something like last year's confusion, and mixes up work and horse-power in a manner truly amazing. This peculiar phase of his own mind is what the *Engineer* designates as the "vagueness" of the word Energy!

But the crowning feat is to come. In a very sensible and able introductory lecture to his engineering class at Leeds, Prof. Barr took occasion to speak of the advantages of preliminary scientific training for engineering students, and protested against the mischievous doctrines too often expressed by so-called "practical men" and their literary champions. He took the opportunity of giving a much-needed warning against the inaccuracies of the *Engineer*; referring (among others) to that already quoted about the failure of the Second Law of Thermodynamics.

He has had his reward! His difference of opinion from the *Engineer* is, of course, to be ascribed to youth, inexperience, want of breadth of knowledge, &c. The *Engineer* goes so far as to suggest such ugly ideas as "disregard for truth"; and, having done so, immediately proceeds to quote me by name as the author of a statement which, with the utmost possible distinctness, I had ascribed to its true author, the late Clerk-Maxwell.

Prof. Barr is quite able to hold his own against such ant-

agonists as the *Engineer*, were they to come, like sorrows, "in battalions":—but what of those many humble but ardent students who have had no scientific instruction, and who have been led by circumstances to rely upon such scientific information as they can pick up from the technical or professional journals, too often the only sources available to them?

That such a question can be asked, and with good reason, in Britain and in this nineteenth century, is a matter for profound humiliation.

How correct is the remark of Paulus Pleydell:—"There are folks before whom one should take care how they play the fool"! The gigantic joke perpetrated in the recent Presidential address to the British Association has been too often taken in earnest, and is already bearing fruit of a very different kind from any that could have been contemplated by the witty author. It is recorded that a practical joker once managed to block up the Strand with gaping idiots, simply by staring at the lion on Northumberland House, and muttering to himself, "It *did* wag." What a comment on this is furnished by the never-to-be-excelled discovery recently made by the *Engineer* that "the Engineer and the Engineer alone is the great civilizer," in whose train "the man of science follows"; with its correlative and complementary theorem "The world owes next to nothing to the man of pure science"!

The *Engineer* may read once more, and (I will hope) with profit, that memoir of Rankine which he has so strangely misquoted. I would commend to his special notice the following lines:—

"(Rankine) did not, indeed, himself design or construct gigantic structures, but he taught, or was the means of teaching, that invaluable class of men to whom the projectors of such works intrust the calculations on which their safety as well as their efficiency mainly depend. For behind the great architect or engineer, and concealed by his portentous form, there is the real worker, without whom failure would be certain. The public knows but little of such men. Not every Von Moltke has his services publicly acknowledged and rewarded by his Imperial employer! But he (*i.e.* the man of pure science) who makes possible the existence of such men confers lasting benefit on his country." P. G. TAIT.

The Great Modern Perversion of Education.

I THINK Mr. Victor Dickins will admit on second thoughts that he has hardly taken pains enough to slay the dragon that confronts him. In his letter to you he says, "I have shown above that competition does not produce any of the evil results complained of in the protest," but the special—if not the only—point to which he addressed himself was, I think, to show that the great prize-winners carried on their success into after-life. Now, the protest never asserted or implied that many prize-winners did not succeed fairly well in after-life. Could this be asserted, the charge against such examinations would be so overwhelming and so easy of proof, that the hours of their survival would be few to count. What the protest asserted was that from time to time—"fairly often," might perhaps stand as the translation of the words "again and again"—the great promise of the brilliant young man comes to nothing; that is to say, this happens sufficiently often to warn us, even if no other warnings existed, that our system may be injuring instead of benefiting, may be restricting and destroying mental powers instead of enlarging them.

The point, however, is not the most fruitful one to discuss. It occupied but an insignificant position in the protest—I think less than six full lines in a paper amounting to about three hundred—and, as far as I know, is not a point on which any one of the assailants of competitive examinations has laid much stress. And one reason is plain. We should all differ so much as to what is success. If you pointed me out either a lawyer who successfully stated his case, a public man who got up a question in a few days, and at the end of the time embodied his remedy in a popular Bill to be laid before the House, or a journalist who came down to his office and wrote a brilliant article upon both the evil and the remedy, whilst admitting the useful qualities that each possessed, I should not consider that such qualities —however vigorously and effectively displayed—necessarily afforded any justification of a particular course of educational training. The world has need of such qualities; it rewards them liberally; and whether competitive examinations exist or not, such qualities will abound quite sufficiently under our present conditions.

If, on the other hand, it could be shown that Mr. Robert Browning, Lord Tennyson, Mr. Herbert Spencer, Mr. Darwin, Mr. Huxley, Mr. J. S. Mill, Mr. Buckle, the two Stephensons, the Duke of Wellington, and many such another, had been the product of competitive examinations, I should at once admit that the defenders of the system had greatly strengthened their case by showing that such training could—if not produce—at least not destroy some of the higher excellencies of mind. But I am afraid that no list of fairly successful politicians or lawyers or doctors enjoying fair practice will affect the case in a vital way. Success of an ordinary kind indicates certain valuable qualities, but they are not the qualities, I submit, that should indicate what form the higher education should take.

If Mr. Dickins writes to arrest the movement that has begun, there are certain points to which I think he should address himself,—points, that if he can successfully deal with, he will deprive us remonstrants of much public sympathy. We charge competitive examinations with lowering the higher motives that belong to education, and exercising a bad intellectual and moral influence upon both pupil and teacher. Admitting a good side,—admitting that success in examination implies self-denial and perseverance, and probably such qualities as quick perception, readiness, and good memory,—we still say that in presence of these great examinations the student learns much of what he has to learn in the wrong way. He cultivates what has been called the portative memory. He learns so as to forget. He loads himself with an immense quantity of detailed knowledge that no man in practical life desires to possess. He learns so as to make a display of knowledge rather than to be the real master of it. He strains after effect. He gives himself up to calculations and dodges. He studies the question of marks. He is learned in summaries, footnotes, and manuals. He does not follow out for himself the points that arouse his intellectual interest, but he throws himself as much as possible upon skilled guidance. He works under pressure, assimilating but a small part of what he takes in, and looking intently forward to the day of relief. He is without the great ideals that belong to learning. He is not primarily influenced by the desire of cultivating his own faculties, of learning how to know, of understanding the world in which he has to live; but by the desire of obtaining a favourable verdict from the man who holds the scales by which his success or his failure is to be determined. It is a highly artificial system, and gives throughout a wrong twist to the student's mind, just like the older system of disputations, which is said to have lowered the sacredness of truth, and to have led men into every shift and wile to disallow their ignorance or the weakness of their cause.

Now, these are general statements, and therefore they apply more to certain kinds of examinations than to others; and to certain characters than to others. It is perfectly true that what Mr. Latham calls art-matter can be tested with less injury to the student than knowledge-matter. That is to say, that you can examine a student more profitably to himself in the arts of playing an instrument, performing a dissection, working a mathematical problem, or translating a language, than you can examine him as regards his knowledge of history, literature, philosophy, or natural science. But, in the first place, he would be a bold man who would propose to fashion education according to the necessities of examination, and only to teach those subjects which lent themselves to examination. In the second place, all arts and all knowledge are so intimately allied, that it is easy to see what a narrowing and stunting influence, as regards intellectual development, there would be in a system that demanded anatomy without physiology, a power of translating a language without other knowledge of the history or literature or genius of such language, that demanded even in music simply a power of execution, and in mathematics simply an unlimited ingenuity in working problems on paper. Let anyone think steadily of such treatment of any of these subjects, and he will, I suspect, escape with difficulty from a sense of nightmare; especially if he think of a whole generation of young minds so manipulated for the sake of the examiners. In the third place, of all the undesirable things to achieve, a generally recognized standard of how to do a thing is the most undesirable. Such a standard you must have, when the examined are brought together from all parts of the kingdom to compete in the same examination; and a better-laid plan for the gradual degradation of an art can scarcely be conceived. We ought by now to have learnt this great truth, that standards which make for uniformity are the greatest enemies of improvement.

As regards the teachers, the effect must be as disastrous as

regards the pupils. If the learner cannot learn in the right way, it follows that the teacher cannot teach in the right way. He necessarily becomes an accomplice in the pressure, the hurry, the preparation for a special moment, the skilful handling of a subject so that a sort of examiner's essence may be extracted from it, and nothing more. Just as the pupil must treat many great subjects in an unworthy manner, not giving himself up wholly and devotedly to them; not following out the many questionings which such subjects naturally arouse in minds which have not lost their freshness and originality, not seeking the higher ends,—love of knowledge and the power of understanding this life which we all have to live,—but engrossed in what, from the point of view of self-cultivation, are the lower ends,—the desire of an intellectual triumph, and perhaps of the position which may reward the triumph,—so must the teacher co-operate hand in hand and step by step in all these inferior motives and inferior uses of a great vocation. Indeed, he will be fortunate if after some years of such work he resist the cynical influence which belongs to the system, and do not begin to believe that both young men and their teachers were specially designed for contests in intellectual cockpits, and that in no other way could the young be induced to forego the pleasures and attractions of life at twenty. I have keen recollections of an old keeper, who used greatly to impress my schoolboy's mind by the intense conviction that he had, that a cock would not have known how to use its spurs, a pike would not have been blessed with its appetite for a silvered spoon, and a fox with its scent, if some ulterior intentions had not existed somewhere on behalf of English sportsmen. Had he only understood our educational system, perhaps he would as stoutly have maintained that our young men were born to be examined, and their seniors to examine them. AUBERON HERBERT.

Old House, Ringwood, November 18.

Mr. Dyer on Physiological Selection.

IF the strength of a theory may be measured by the weakness of criticism, I have good reason to be hopeful for the future of "Physiological Selection." On this account I am glad that Mr. Dyer has sought to justify his remarks by giving his reasons for them, although I regret what appears to me the needless asperity of his tone. However, disregarding the personalities in which he has clothed his reply, I will endeavour to show that the reply itself is about as unfortunate as a reply could well be.

Taking his points *seriatim*, I am in no way responsible for the notices of my paper which appeared in the *Times* or in any other periodical, except, of course, those which I have published with my own signature. But, although not responsible for what the newspapers said, I should have corrected any "absurd misrepresentation," had I met with such. The passage, however, which Mr. Dyer now quotes from the *Times* of more than two years ago (and which, I presume, is correctly quoted) does not appear to me a misrepresentation at all. On the contrary, I gather from it that the writer must have perfectly well understood my paper. What he states is that, in my view, natural selection is a theory of the origin of adaptations "*rather*" than a theory of the origin of species. Mr. Dyer appears to regard this as identical with his own statement—viz. that in my view natural selection is not in any sense a theory of species, but "*only* of adaptations." In other words, the former statement correctly imputes to me the opinion that Mr. Darwin's theory is *primarily* a theory of adaptations wherever these occur, and, consequently, *also* a theory of species in every case where species differ from one another in respect of adaptive characters; while the latter affirms unequivocally that in my opinion "specific differences are not adaptive," and, consequently, that Mr. Darwin's theory is a theory of adaptations *to the total exclusion of species*—for an explanation of the origin of which "it follows that we must look to Mr. Romanes himself." Now I must say that if Mr. Dyer cannot see the distinction between these two statements, I may well cease to regret on my own account the difficulty which he says he experiences in understanding my papers.

But although it does not appear that the *Times* misunderstood me in this matter, it is quite true that Mr. Wallace did; and soon after my paper was published, he misrepresented me in exactly the same way as Mr. Dyer misrepresents me now. But I immediately and most emphatically repudiated this astonishing interpretation at the time, in a general answer to criticisms which was published in the *Nineteenth Century* for January 1887. Therefore, whatever Mr. Dyer may think about the reiterated contradiction which I gave in these columns a week or two ago, he is plainly and entirely in the wrong where he refers to it as "a denial that comes rather late in the day." He appears to have adopted Mr. Wallace's interpretation without deeming it worth his while to glance at my reply, before republishing to his audience at Bath a misrepresentation which I had long ago repudiated with all the resources of the English language that I could command.

Why, indeed, any such "denial" on my part should ever have been required has always been to me unintelligible. The original paper itself over and over again insists that I do not at all doubt the important (though, as Darwin says, "not exclusive") part which natural selection has played in the origination of species. Some of these passages I republished in my last letter (October 25), and thus it is for your readers to judge whether the smallest degree of ambiguity attaches to them. But, again ignoring these passages, even as now re-quoted, italicized, and especially addressed to himself, Mr. Dyer seeks to justify what I have now so often had to designate as this "absurd" rendering of my views, by pointing out that in my paper one of the sections is headed "Natural Selection not a Theory of the Origin of Species." This is the only justification that he attempts. Let us see what it is worth.

I readily acknowledge that, to have been quite accurate, the heading of this section ought to have been "Natural Selection not strictly speaking a Theory of the Origin of Species." But I submit that the oversight of here leaving out the words "strictly speaking" (which are elsewhere supplied), was an oversight which could not possibly have misled any reader as to my meaning—unless, of course, he confined himself to reading only the headings of my sections. For it was in the short section thus headed that the very passages occur which I selected from my whole paper to quote in my last letter, as furnishing "direct contradiction" to Mr. Dyer's statement. In other words, following immediately and repeatedly upon the heading in question, there are passages which carefully and unequivocally guard against the very imputation which Mr. Dyer now seeks to force upon me. As a critic of my writings, therefore, he is here trebly in the wrong. First, because his statement of my views admits of being flatly falsified by my original paper itself;[1] secondly, because he ignores all that I have since written upon the same subject; and thirdly, because he now fails to withdraw what I have told him is a travesty of my meaning.

But even this is not all. For Mr. Dyer goes on to say:—"Everybody knows that the idea of evolution of organic Nature existed in men's minds long before Mr. Darwin. He did not originate it; what he did originate was the theory that 'natural selection' is the mechanical means by which that evolution has been brought about. Mr. Romanes says roundly that it is not, or words have ceased to have meaning." Now, if, *without divorcing them from their immediate context*, Mr. Dyer will be considerate enough to point to any words which I have ever writen or ever spoken from which such an interpretation as this can, by any amount of twisting, be extracted, I shall indeed begin to believe that words have so far ceased to convey a meaning of any kind as to be practically useless for purposes of expression. Because I have insisted that, in the great drama of "evolution," natural selection has been *everywhere* the one great agent in the causing of adaptations; because I have said that, on this account, we should take much too narrow a view of so vast an agency were we to regard it as concerned *only* in the origin of "species," or as having to do *only* with such adaptations as happen to be of but specific value; because I have advocated a larger and more correct view of the stupendous importance of this "mechanical means" by which *all* "evolution" in organic Nature has been brought about, with the exception only (as I say in my paper) "of mutual sterility and trivial details of structure, form, and colour," which alone I attribute to the "supplementary factor" of physiological selection,—because I have said all these things, Mr. Dyer now tells me that I have roundly denied the agency of natural selection altogether! After this, I can only feel that

[1] For instance:—"Let me not be misunderstood. In saying that the theory of natural selection is not, properly speaking, a theory of the origin of species, I do not mean to say that the theory has had no part at all in explaining such origin. Any such statement would be in the last degree absurd. What I mean to say is that the theory is one which explains the origin and conservation of adaptations, whether structural or instinctive, and whether these occur in species, genera, families, orders, or classes."

it is hopeless to continue discussion with so extraordinary a disputant. Indeed, as he had published this statement in bald and obvious contradiction to all my writings, nothing more remains to be said: I simply challenge justification as plainly impossible.[1]

The next point in Mr. Dyer's criticism is where he says that if a large proportional number of specific differences are, as I allege, useless, this "would be quite as effective as proving the proposition universally in inflicting a deadly blow on the Darwinian theory, the very essence of which is that specific differences must be advantageous." Now this I deny *in toto.* It is no part of the essence of Mr. Darwin's theory to assume that all specific characters must be advantageous, nor does it even belong to this theory to decide in what proportion as to number advantageous characters stand to indifferent ones. Without going over the ground already traversed with regard to this matter in my previous letter, perhaps it may produce some effect on Mr. Dyer's mind if I quote Mr. Darwin's own opinion upon the subject. After stating what *would* be "absolutely fatal" to his theory, he proceeds (italics here and elsewhere mine), "I fully admit that *many* structures are now of no use to their possessors, and may never have been of any use to their progenitors. . . . *It is scarcely possible to decide* how much allowance ought to be made for such causes of change as the definite action of external conditions, so-called spontaneous variations, and the complex laws of growth; but, *with these important exceptions*, we may conclude that the structure of every living creature either now is, or formerly was, of some direct or indirect use to its possessor" ("Origin of Species," sixth edition, p. 160). Mr. Huxley expresses himself to exactly the same effect in his recently-published obituary notice, where he says that, so far as the theory of natural selection is concerned, a species may present "*any number*" of characters "which are neither advantageous nor disadvantageous, but indifferent, or even slightly disadvantageous" (Proc. R.S., vol. xliv. No. 269, p. xviii.). After all the controversy which I have had upon this subject with Mr. Wallace, I am exceedingly glad to find Mr. Huxley speaking out so "roundly" on the Darwinian side of it. Mr. Dyer, indeed, still objects that he thinks "Mr. Huxley is disposed to make too great concessions." Of course Mr. Dyer is entitled to have his own opinion upon the matter; but I submit he is not entitled to set up this opinion as so authoritative that I am *ipso facto* bound to accept its statement as constituting the very essence of the Darwinian theory. No doubt "with regard to plants" he is "competent to speak"; but he must surely be aware that other botanists who have more thoroughly considered this question are dead against him in his general conclusion. In particular, the late Prof. Nägeli made this subject the matter of a careful inquiry "with regard to plants," the result of which was very materially to influence the judgment of Mr. Darwin.[2]

Next, Mr. Dyer says that because I am not what he calls a "practised naturalist," my "method is the very inverse of that of Mr. Darwin." Now, without at all recognizing Mr. Dyer's right to lecture in this way on the subject of scientific research, I may nevertheless refer him to the history of every other theory which has ever been published with reference to generation, from the "provisional hypothesis" of pangenesis by Darwin himself, through the plastidule of Haeckel and the idio-plasma of Nägeli, to the keim-plasma of Weismann. In all these cases the "method" has been the same as mine—viz. to collate the known facts bearing on the principle suggested, and to leave for future work such experimental verification as may be possible. Moreover, even the theory of natural selection (to which, I suppose, Mr. Dyer more especially alludes) was established by general reasonings from the bringing together of facts already known;[3] and when we remember the much greater importance of this theory, as well as the whole change of thought which it has produced with reference to the general doctrine of evolution, I cannot feel that, relatively speaking, I was over-precipitate in publishing my views on physiological selection.

Further on Mr. Dyer objects to my names for the principle in debate—*i.e.* "physiological selection" and "segregation of the fit"—and says he is "surprised that Mr. Romanes has taken so far no notice" of this objection as originally presented in the *Times.* But here again "the demon of inaccuracy" pursues him. In my general reply to criticisms, already referred to above, and prominently so in these columns at the time, I fully considered this objection; and therefore, if on my side there were still any room left for "surprise," I might have here expressed a certain degree of wonder that before writing the letter which he has now published he should not have taken the trouble to read the author whom he is somewhat intemperately attacking.[1]

In point of fact, however, his attack is everywhere delivered with so complete an absence of judgment, as well as of information on what he is writing about, that it amounts to a mere hitting at random. This, I think, I have now sufficiently proved. Nevertheless, although truly "rather late in the day," I commend to his consideration my article in the *Nineteenth Century* of nearly two years ago, as disposing still more effectually than space will here permit of every one of his general statements and detailed objections. I may add that the bias shown by thus repeating borrowed criticisms, without first consulting my answers, quite deprives his opinion, in my estimation, of the weight to which I might otherwise have felt that it was entitled.

In conclusion, it is useless to conjecture with Mr. Dyer what Mr. Darwin would have thought of physiological selection as a theory; and I have already given my reasons for holding it improbable that he ever considered it (NATURE, vol. xxxiv. p. 545). On the other hand, I should like to remark, that although what he complained of as "the great power of steady misrepresentation"[2] has seriously prejudiced the theory in this country, such has not been the case abroad, where in many quarters it has been received with unqualified favour. This remark—which applies to botanical as well as zoological authority—is added merely in order that the theory may have fair play.

GEORGE J. ROMANES.

Geanies, Ross-shire, N.B., November 4.

P.S.—Proofs of this letter have been accidentally delayed in transmission.—G. J. R., Edinburgh, November 22.

Cleistogamy.

I SHOULD like to add a few words to the extract from the minutes of the Scientific Committee of the Royal Horticultural Society, quoted in NATURE, November 22, p. 86. The causes of the cleistogamous condition of some of the plants mentioned I would attribute to their stunted habit induced by mowing, coupled with a relatively cold season. For, while some of them, *e.g. Cerastium*, *Montia*, and *Alchemilla*, rarely open their buds, the *Veronica*, *Sagina*, and *Trifolium*, are more inclined to do so, if allowed to grow more vigorously, and if the temperature be higher. Cleistogamy is of course only a relative quality. Thus chickweed and spurry will open their flowers widely in hot weather; but are cleistogamous and abundantly self-fertile all

[1] In another part of his letter Mr. Dyer says that my theory of physiological selection "shrivels up the part played by natural selection to very small dimensions." Here, again, I can only request that some explanation should be given of the process of reasoning whereby my critic has arrived at this most astonishing conclusion.

[2] "I now admit, after reading the essay by Nägeli on plants, and the remarks by various authors with respect to animals, more especially those recently made by Prof. Broca, that in earlier editions of my 'Origin of Species' I perhaps attributed too much to the action of natural selection. . . . I did not formerly consider sufficiently the existence of structures, which, as far as we can at present judge, are neither beneficial nor injurious; and this I believe to be one of the greatest oversights as yet detected in my work."—"Descent of Man," second edition, p. 61. See also, for emphatic passages to the same effect in the "Origin of Species," sixth edition, pp. 171, 176, 421.

[3] "Belief in natural selection must at present be grounded entirely on general considerations, ... and chiefly from this view connecting under an intelligible point of view a host of facts."—Letter of Darwin to Bentham, "Life," &c., iii. p. 25.

[1] The following is what I said with regard to this criticism in the *Nineteenth Century* for January 1887, and it leaves nothing further to be said now:—"This is a point of no real importance, and I readily concede that in some respects physiological isolation would be a better name than physiological selection. The reasons which inclined me to adopt the latter in preference to the former will be gathered from what has just been said. If the theory is sound at all, a process of true survival takes place, in some cases of the primary [*i.e.* sexual], in other cases of those secondary [*i.e.* morphological] specific characters which are capable of inducing the primary; and in either event it is only certain changes of character, or particular variations, which are *selected* to survive as new species. Moreover, the term physiological selection does not exclude the term physiological isolation, any more than the term natural selection excludes the term survival of the fittest. . . . The 'fitness' of the individuals affected is guaranteed by the fact of their having reached the breeding age. This latter point is important, because Mr. Wallace accuses me of having lost sight of the consideration that my physiological variations must conform to the law of natural selection. . . . If these physiological varieties ever occur at all, *ex hypothesi* they must have so far passed muster with respect to general fitness as to be allowed to propagate their kind. It was for the sake of emphasizing this feature of my theory that I gave the latter the alternative title of 'segregation of the fit.'"

[2] "Origin of Species," p. 421. The whole paragraph, read in connection with the present controversy, is curiously interesting, and to me very consoling. Moreover, the scientific creed which it rehearses is in every particular identical with my own, while differing considerably from that of my critic.

through autumn and winter, if it be mild. With regard to *Trifolium subterraneum*, as it was about thirty years ago when observed it, I cannot now be certain that it was actually cleistogamous; but it grew with just the same habit as the above, and was most probably self-fertile as they are.

GEORGE HENSLOW.

Nose-Blackening as Preventive of Snow-Blindness.

I BEG to send you an extract from a letter just received from my son, of the Indian Geological Survey Department, and who is at present engaged by the Maharajah of Kashmir in exploring and reporting on his sapphire mines. Since it refers to former communications in NATURE (vol. xxxviii. pp. 7 and 101), upon a subject of interest to travellers, it may be of use.

I may here mention that my son speaks of having found the Eocene Nummulitic limestone in Zanskar at a height of 18,500 feet above the sea. Sir J. D. Hooker tells me that he has previously observed the Nummulites in Tibet, at a height of 18,000 feet.

J. D. LA TOUCHE.

Stokesay, Craven Arms, November 20.

"Some time ago there was a letter in NATURE describing a method of protecting the eyes from sun-glare, when crossing snow, by blackening the nose and cheeks under the eyes. I tried the dodge the other day, when I was crossing the snow-fields and glaciers from Zanskar, and found it very successful. My shikari and some of the other natives were much amused when I produced a piece of charcoal, and proceeded to blacken my face; but they also tried it, and said that it relieved them very much. I do not know how the effect is produced, but it was much the same as when one went off the snow on to a patch of moraine or rocks clear of snow. The blackening seemed to stop the reflected rays in some way. The natives expressed the feeling by saying that it cooled their faces. I found it quite possible to walk over the snow for many miles without glasses, which are a nuisance, especially on rough ground; but without the blackening I had to put them on. The sun at these high altitudes has much greater effect than in England when the ground is covered with snow."

Amber.

IN NATURE (vol. xxxvi. p. 63), I find the following note:—"The largest piece of amber ever discovered was recently dug up near the Nobi's Gate, at Altona. It weighed 850 grammes." I beg to state that a piece of amber, weighing 5·6 kilogrammes, is in the possession of Messrs. Stantien and Becker, in Königsberg, and that pieces weighing 6·5 and 9·5 kilogrammes can be seen in the Berlin Mineralogical Museum, both discovered off the sea coast of North Germany. Even as far inland as Silesia, a piece of Baltic amber, weighing 3 kilogrammes, has been found in the bed of the River Oder, near Breslau. Baltic amber occurs in Silesia also as high as 1400 feet above the level of the sea.

A. B. MEYER.

Royal Museum, Dresden, November 19.

ON THE MECHANICAL CONDITIONS OF A SWARM OF METEORITES.[1]

II.

THE next point to consider is the mass and size which must be attributed to the meteorites.

The few samples which have been found on the earth prove that no great error can be committed if the average density of a meteorite be taken as a little less than that of iron, and I accordingly suppose their density to be six times that of water.

Undoubtedly in a meteor-swarm all sizes co-exist (a supposition considered hereafter); for even if originally of uniform size they would, by subsequent fracture, be rendered diverse. But in the first consideration of the problem they have been treated as of uniform size; and, as actual sizes are nearly unknown, results are given for meteorites weighing $3\frac{1}{8}$ grammes. From these, the values for other masses are easily derivable. It is known that meteorites are actually of irregular and angular shapes, but certainly no material error can be incurred when we treat them as being spheres.

The object of all these investigations is to apply the formulæ to a concrete example. The mass of the system is therefore taken as equal to that of the sun, and the limit of the swarm at any arbitrary distance from the present sun's centre. The theory is of course more severely tested the wider the dispersion of the swarm, and accordingly in a numerical example the outside limit of the solar swarm is taken at $44\frac{1}{2}$ times the earth's distance from the sun, or further beyond the planet Neptune than Saturn is from the sun. This assumption makes the limit of the isothermal sphere at a distance 16, about half-way between Saturn and Uranus.

In this case the mean velocity of the meteorites in the isothermal sphere is $5\frac{1}{3}$ kilometres per second, being $\sqrt{\frac{6}{5}}$ of the linear velocity of a planet revolving about a central body with a mass equal to 46 per cent. of that of the sun, at distance 16. In the adiabatic layer it diminishes to zero at distance $44\frac{1}{2}$. This velocity is independent of the size of the meteorites. The mean free path between collisions ranges from 42,000 kilometres at the centre, to 1,300,000 kilometres at radius 16, and to infinity at radius $44\frac{1}{2}$. The mean interval between collisions ranges from a tenth of a day at the centre, to three days at radius 16, and to infinity at radius $44\frac{1}{2}$. The criterion of applicability of hydrodynamics ranges from $\frac{1}{60000}$ at the distance of the asteroids, to $\frac{1}{3600}$ at radius 16, and to infinity at radius $44\frac{1}{2}$.

All these quantities are ten times as great for meteorites of $3\frac{1}{8}$ kilogrammes, and a hundred times as great for meteorites of $3\frac{1}{8}$ tonnes.

From a consideration of the tables in the paper it appears that, with meteorites of $3\frac{1}{8}$ kilogrammes, the collisions are sufficiently frequent even beyond the orbit of Neptune to allow the kinetic theory to be applicable in the sense explained. But if the meteorites weigh $3\frac{1}{8}$ tonnes, the criterion ceases to be very small at about distance 24; and if they weigh 3125 tonnes, it ceases to be very small at about the orbit of Jupiter. It may be concluded then that, as far as frequency of collision is concerned, the hydrodynamical treatment of a swarm of meteorites is justifiable.

Although the numerical results are necessarily affected by the conjectural values of the mass and density of the meteorites, yet it was impossible to arrive at any conclusion whatever as to the validity of the theory without numerical values, and such a discussion as the above was therefore necessary.

I now pass on to consider some results of this view of a swarm of meteorites, and to consider the justifiability of the assumption of an isothermal-adiabatic arrangement of density.

With regard to the uniformity of distribution of kinetic energy in the isothermal sphere, it is important to ask whether or not sufficient time can have elapsed in the history of the system to allow of the equalization by diffusion.

It is shown therefore in the paper that in the case of the numerical example primitive inequalities of kinetic energy would, in a few thousand years, be sensibly equalized over a distance some ten times as great as our distance from the sun. This result, then, goes to show that we are justified in assuming an isothermal sphere as the centre of the swarm. As, however, the swarm contracts, the rate of diffusion diminishes as the inverse $\frac{5}{2}$ power of its linear dimensions, whilst the rate of generation of inequalities of distribution of kinetic energy, through the imperfect elasticity of the meteorites, increases. Hence, in a late stage of the swarm, inequalities of kinetic energy would be set up, there would be a tendency to the production of convective currents, and

[1] Abstract of a Paper read before the Royal Society on November 15 by Prof. G. H. Darwin, F.R.S. Continued from p. 83.

thus the whole swarm would probably settle down to the condition of convective equilibrium throughout.

It may be conjectured, then, that the best hypothesis in the early stages of the swarm is the isothermal-adiabatic arrangement, and later an adiabatic sphere. It has not seemed worth while to discuss this latter hypothesis in detail at present.

The same investigation also gives the coefficient of viscosity of the quasi-gas, and shows that it is so great that the meteor-swarm must, if rotating, revolve nearly without relative motion of its parts, other than the motion of agitation. But as the viscosity diminishes when the swarm contracts, this would probably not be true in the later stages of the history, and the central portion would probably rotate more rapidly than the outside. It forms, however, no part of the scope of this paper to consider the rotation of the system.

The rate of loss of kinetic energy through imperfect elasticity is next considered, and it appears that the rate, estimated per unit time and volume, must vary directly as the square of the qaasi-pressure, and inversely as the mean velocity of agitation. Since the kinetic energy lost is taken up in volatilizing solid matter, it follows that the heat generated must follow the same law. The mean temperature of the gases generated in any part of the swarm depends on a great variety of circumstances, but it seems probable that its variation would be according to some law of the same kind. Thus, if the spectroscope enables us to form an idea of the temperature in various parts of a nebula, we shall at the same time obtain some idea of the distribution of density.

It has been assumed that the outer portion of the swarm is in convective equilibrium, and therefore there is a definite limit beyond which it cannot extend. Now a medium can only be said to be in convective equilibrium when it obeys the laws of gases, and the applicability of those laws depends on the frequency of collisions. But at the boundary of the adiabatic layer the velocity of agitation vanishes, and collisions become infinitely rare. These two propositions are mutually destructive of one another, and it is impossible to push the conception of convective equilibrium to its logical conclusion. There must, in fact, be some degree of rarity of density and of collisions at which the statistical treatment of the medium breaks down.

I have sought to obtain some representation of the state of things by supposing that collisions never occur beyond a certain distance from the centre of the swarm

Then from every point of the surface of the sphere, which limits the region of collisions, a fountain of meteorites is shot out, in all azimuths and at all inclinations to the vertical, and with velocities grouped about a mean according to the law of error. These meteorites ascend to various heights, without collision, and, in falling back on to the limiting sphere, cannonade its surface, so as to counterbalance the hydrostatic pressure at the limiting sphere.

The distribution in space of the meteorites thus shot out is investigated in the paper, and it is found that near the limiting sphere the decrease in density is somewhat more rapid than the decrease corresponding to convective equilibrium.

But at more remote distances the decrease is less rapid, and the density ultimately tends to vary inversely as the square of the distance from the centre.

It is clear that according to this hypothesis the mass of the system is infinite in a mathematical sense; for the existence of meteorites with nearly parabolic and hyperbolic orbits necessitates an infinite number, if the loss of the system shall be made good by the supply.[1]

But if we consider the subject from a physical point of view, this conclusion appears unobjectionable. The ejection of molecules with exceptionally high velocities from the surface of a liquid is called evaporation, and the absorption of others is called condensation. The general history of a swarm, as sketched at the beginning, may be put in different words, for we may say that at first a swarm gains by condensation, that condensation and evaporation balance, and finally that evaporation gains the day.

If the hypothesis of convective equilibrium be pushed to its logical conclusion, we reach a definite limit to the swarm, whereas if collisions be entirely annulled the density goes on decreasing inversely as the square of the distance. The truth must clearly lie between these two hypotheses. It is thus certain that even the small amount of evaporation shown by the formulæ derived from the hypothesis of no collision must be in excess of the truth; and it may be that there are enough waifs and strays in space ejected from other systems to make good the loss. Whether or not the compensation is perfect, a swarm of meteorites would pursue its evolution without being sensibly affected by a slow evaporation.

Up to this point the meteorites have been considered as of uniform size, but it will be well to examine the more truthful hypothesis that they are of all sizes, grouped about a mean according to a law of error.

It appears, from the investigation in the paper, that the larger stones move slower, the smaller ones faster, and the law is that the mean kinetic energy is the same for all sizes. It is proved that the mean path between collisions is shorter in the proportion of 7 to 11, and the mean frequency of collision greater in the proportion of 4 to 3, than if the meteorites were of uniform mass equal to the mean. Hence the numerical results found for meteorites of uniform size are applicable to non-uniform meteorites of a mean mass about a third greater than the uniform mass; for example, the results for uniform meteorites of $3\frac{1}{8}$ tonnes apply to non-uniform ones of mean mass a little over 4 tonnes.

The means here spoken of refer to all sizes grouped together, but there is a separate mean free path and mean frequency appropriate to each size. These are investigated in the paper, and their values illustrated in a figure. It appears that collisions become infinitely frequent for the infinitely small ones, because of their infinite velocity, and again infinitely frequent for the infinitely large ones, because of their infinite size. There is a minimum frequency of collision for a certain size, a little less in radius than the mean radius, and considerably less in mass than the mean mass.

For infinitely small meteorites the mean free path reaches a finite limit, equal to about four times the grand mean free path; and for infinitely large ones, the mean free path becomes infinitely short. It must be borne in mind that there are infinitely few of the infinitely large and infinitely small meteorites. Variety of size does not then, so far, materially affect the results.

But a difference arises when we come to consider the different parts of the swarm. The larger meteorites, moving with smaller velocities, form a quasi-gas of less elasticity than do the smaller ones. Hence the larger meteorites are more condensed towards the centre than are the smaller ones, or the large ones have a tendency to fall down, whilst the small ones have a tendency to rise. Accordingly, the various kinds are to some extent sorted according to size.

An investigation is made in the paper of the mean mass of meteorites at various distances from the centre, both inside and outside of the isothermal sphere, and a figure illustrates the law of diminution of mean mass.

It is also clear that the loss of the system through evaporation must fall more heavily on the small meteorites than on the large ones.

After the foregoing summary, it will be well to briefly

[1] It must also be borne in mind that the very high velocities which occur occasionally in a medium with perfectly elastic molecules, must happen with great rarity amongst meteorites. An impact of such violence that it *ought* to generate a hyperbolic velocity will probably merely cause fracture.

recapitulate the principal physical conclusions which seem to be legitimately deducible from the whole investigation; in this recapitulation qualifications must necessarily be omitted or stated with great brevity.

When two meteorites are in collision, they are virtually highly elastic, although ordinary elasticity must be nearly inoperative.

A swarm of meteorites is analogous with a gas, and the laws governing gases may be applied to the discussion of its mechanical properties. This is true of the swarm from which the sun was formed, when it extended beyond the orbit of the planet Neptune.

When the swarm was very widely dispersed, the arrangement of density and of velocity of agitation of the meteorites was that of an isothermal-adiabatic sphere. Later in its history, when the swarm had contracted, it was probably throughout in convective equilibrium.

The actual mean velocity of the meteorites is determinable in a swarm of given mass, when expanded to a given extent.

The total energy of agitation in an isothermal-adiabatic sphere is half the potential energy lost in the concentration from a condition of infinite dispersion.

The half of the potential energy lost, which does not reappear as kinetic energy of agitation, is expended in volatilizing solid matter, and heating the gases produced on the impact of meteorites. The heat so generated is gradually lost by radiation.

The amount of heat generated per unit time and volume varies as the square of the quasi-hydrostatic pressure, and inversely as the mean velocity of agitation. The temperature of the gases volatilized probably varies by some law of the same nature.

The path of a meteorite is approximately straight, except when abruptly deflected by a collision with another. This ceases to be true at the outskirts of the swarm, where the collisions have become rare. The meteorites here describe orbits under gravity which are approximately elliptic, parabolic, and hyperbolic.

In this fringe to the swarm the distribution of density ceases to be that of a gas under gravity; and as we recede from the centre the density at first decreases more rapidly, and afterwards less rapidly than if the medium were a gas.

Throughout all the stages of its history there is a sort of evaporation by which the swarm very slowly loses in mass, but this loss is more or less counterbalanced by condensation. In the early stages the gain by condensation outbalances the loss by evaporation; they then equilibrate, and finally the evaporation may be greater than condensation.

Throughout the swarm the various meteorites are to some extent sorted according to size; as we recede from the centre the number of small ones preponderates more and more, and thus the mean mass continually diminishes with increasing distance. The loss by evaporation falls principally on the small meteorites.

A meteor swarm is subject to gaseous viscosity, which is greater the more widely diffused is the swarm. In consequence of this a widely extended swarm, if in rotation, will revolve like a rigid body without relative motion (other than agitation) of its parts.

Later in the history the viscosity will probably not suffice to secure uniformity of rotation, and the central portion will revolve more rapidly than the outside.

The kinetic theory of meteorites may be held to present a fair approximation to the truth in the earlier stages of the evolution of the system. But later, the majority of the meteors will have been absorbed by the central sun and its attendant planets, and amongst the meteors which remain free the relative motion of agitation must have been largely diminished. These free meteorites—the dust and refuse of the system—probably move in clouds, but with so little remaining motion of agitation that (except perhaps near the perihelion of very eccentric orbits) it would scarcely be permissible to treat the cloud as in any respect possessing the mechanical properties of a gas.

The value of this whole investigation will appear very different to different minds. To some it will stand condemned as altogether too speculative; others may think that it is better to risk error in the chance of winning truth. To me, at least, it appears that this line of thought flows in a true channel; that it may help to give a meaning to the observations of the spectroscopist; and that many interesting problems, here barely alluded to, may perhaps be solved with sufficient completeness to throw light on the evolution of nebulæ and planetary systems.

EDISON'S PERFECTED PHONOGRAPH.

THE marvellous results attained by Mr. Edison's recent improvement on, or, more properly perhaps, resurrection of, the original phonograph of 1878 have induced us to present a view of the latest form of the instrument, together with a short description of its main features and most recent performances.

Mr. Edison is still occupied in perfecting the instrument, and scarcely a week passes without his sending over to his European colleague, Colonel Gouraud, substantial evidences of progress towards perfecting the arrangements either for the recording and reproducing of all kinds of sounds, or else in the construction and the postal conveyance of phonograms.

Although, therefore, the instrument can hardly at present be said to have reached its final stage of development, in its chief constructive points it may be regarded as practically perfected; while some recent trials of it show that it is capable not merely of recording, but of reproducing, every kind of sound with which we are acquainted, including articulate speech, with a fidelity little short of absolute perfection.

When Léon Scott invented his phonautograph, he unconsciously came near the phonograph, though he merely contented himself with reproducing the vibrations pictorially on a blackened surface. Prof. Helmholtz, on the other hand, by his profound studies in the analysis and synthesis of speech into fundamentals, accompanied by varying combinations of subsidiary harmonics, seems to have created quite a scare among the phonographists, by showing them what a terribly complicated affair articulate speech was. In the phonograph, however, we have a machine which not only differentiates all these complicated systems of vibrations, checks, and harmonics, but integrates them equally well. It is, moreover, capable of repeating the integrations practically as often as we please.

This perfected power of record, reproduction, and preservation of sound has been accomplished partly through the substitution of a specially prepared wax for the original tinfoil, but also a good deal through other improvements in the diaphragms, needles, &c. The vibrations of the recording diaphragm are transferred by means of a cutting-needle to the wax, which is thus carved and indented into a series of hills and valleys, which represent in *intaglio* the resultant form of the original sound-vibrations, including part, if not all, of the minor inflections due to the presence of the subsidiary harmonics or overtones.

The tinfoil used in the original machine of 1878 only very partially fulfilled the office of a recording surface, and since every indentation in it necessarily involved a corresponding rise of the material on either side, the vibrations of the recording style, and *a fortiori* of the air itself, were only very imperfectly reproduced on its surface. The hollow character of the undulations, moreover, caused them to be easily effaced after a few repetitions.

The records on the wax, on the other hand, have been recently reproduced over 3000 times.

As a good many of the specifications describing the new improvements are not yet made public, we are not at liberty to describe minutely the various parts of the instrument. We can, however, give the following outline of its leading features :—

(1) There is a brass cylinder on which the wax phonogram is placed.

(2) A rocking holding arm, which carries what is termed the "spectacle," containing the recording and reproducing diaphragms, and which by means of a traveller arm is made to engage two rotating screws—one called the feeding screw, very finely threaded, which causes it to travel slowly from left to right over the rapidly rotating phonogram, and thus trace out a long spiral on its surface; the other, a coarser reversely-threaded screw, which enables it to be moved back more rapidly opposite any required position on the phonogram. By means of a screw-head attached to a turning bar with an arrangement of cams, the rocking holding arm can be made to engage either the feeding or reversing screw, or else lift the diaphragm and its recording or reproducing needle entirely off the surface of the phonogram. These back and forward movements can be preferably made by a treadle attached to either the turning bar or rocking arm, leaving the hands free for other purposes.

(3) Another very practically useful adjunct consists of a projecting arm attached to the turning bar, by which the operator when desiring to stop and think what he is going to say next can completely disengage the diaphragm and and its accompanying recording needle from the surface

Showing reproducing diaphragm in position, the operator listening through the tubes, and standing behind the instrument so as to allow it to be seen

of the wax; and if the pause is a long one, and he does not desire to waste his phonogram, he can reverse the movement of the diaphragm until it is opposite the point on the phonogram where he left off. By combinations of arrangements of this sort, all the actions of an ordinary writer, stopping to think, looking over, and even correcting what he has written, can be imitated.

(4) The arrangement by which a phonogram can be removed and another replaced, simply consists in having one of the centres on which the brass cylinder turns, attached to a movable arm.

(5) Though, theoretically, one diaphragm could effect both record and reproduction, it is found that the same shape of needle or style is unsuited for both purposes. Consequently, there are two diaphragms, one a recorder and the other a reproducer.

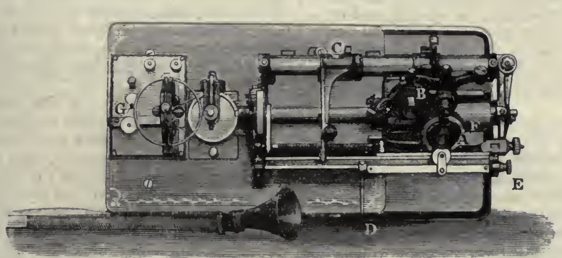
The style of the recording diaphragm is made of such a shape as to be more of the nature of a graving tool, while that attached to the reproducing diaphragm is inclined at an angle to the surface of the wax, and glides over its indentations without destroying them. In front of the recording style is placed the cutting-out tool, whose function is somewhat analogous to the dibble of the gardener. It not only prepares a furrow in the wax in which the record can be made, but it also destroys any previous record. So that the making of a fresh record and the effacing of a previous one can proceed simultaneously.

The use of tubes to the ear raises a point about which a good deal of misapprehension appears to exist. The machine at present is not intended for reproducing sounds with their original intensity, but rather for the perfect reproduction of articulate speech and music. Many persons,

therefore, on hearing the reproduction through the magnifying funnel, are disappointed to find the effect below their expectations. As soon, however, as they listen through the tubes, they are proportionately surprised at the loudness and the clearness of the sound and articulation. While for most practical purposes audition through the tubes is quite sufficient, Mr. Edison is, we understand, constructing a means by which the sounds can be greatly magnified. Even as it is, with the present funnel the reproduction can be heard very well throughout a large room. For example, at a lecture on November 10, before Harrow School, a perfect *mélange* of speaking, singing, and whistling, made by Colonel Gouraud on the spot, was plainly heard all over the lecture theatre, in which about 600 persons were present.

Other improvements comprise an electric motor and speed governor, by which the phonogram and the feeding screws can be rotated at a constant speed. As this electric motor is itself the subject of a separate patent, we are only at liberty to say that it is an electro-dynamic multipolar motor, in which a ring armature acts as a fly-wheel, and that it is adjustable to different speeds—a necessary point in order to preserve the same pitch where the rapidity of utterance is subject to variation. The circuiting of the motor and governor is ingeniously arranged so that the field of the armature can be opened without interfering with the field-magnet circuit, thus securing greater sensitiveness and an absence of sparking.

The phonograms themselves are divided into two sorts, office-grams and mailing-grams. The former are cylinders, capable at the present time of yielding from thirty to fifty surfaces for record, which number, as Mr. Edison says in a letter only received a few days ago, can now, by improved methods, be increased to two hundred. Obviously, however, such a cylinder would be an awkward affair to send by post. Mr. Edison has therefore



Instrument turned over so as to present a top view with recording diaphragm in position. A, recording diaphragm; B, reproducing diaphragm; C, rocking holding arm; D, bar for arresting record; E, turning bar; F, wax cylindrical phonogram; G, electric speed governor.

met this want by constructing the mailing-gram, and though this may seem a small matter from a scientific point of view, yet we venture to prophesy that among all his many achievements there will be none to which he will look back with greater pride, or which are destined to work a greater revolution in the history of the world than this apparently simple little mailing-gram. To say that it is capable of being posted, and reproduced at the other end without injury to the record, may perhaps give some idea of its practical value.

Regarding the way in which all this is accomplished, it is needless to say anything, except that the device bears the true stamp of genius, viz. simplicity. This portability of the phonograms is, in fact, one of the salient features by which the phonograph of 1888 stands out in marked contrast to the imperfect machine of 1878, and this improvement, in combination with the greater perfection and permanence of the record, at once raises it from the level of a pretty scientific toy or curiosity to one of immediate utility.

The practical working of the instrument, which has been greatly improved even upon what it was at the meeting of the British Association at Bath this year, may be gathered from the fact that Colonel Gouraud dictates all his correspondence through it, speaks to it in different languages, applies every conceivable test to try its powers, and with results which not only astonish him and everybody else, but even the inventor himself.

The purposes to which such an instrument can be applied—scientific, commercial, domestic, artistic, military—seem countless. The dreams which were indulged in when the phonograph of 1878 appeared, can now be realized; and we owe to Mr. Edison another substantial addition to the long list of direct results of scientific labour achieved during the present century.

FURTHER NOTES ON THE LATE ERUPTION AT VULCANO ISLAND.

MY friend Signor Gaetano Platania, who accompanied me on my trip through the Lipari Islands in June 1887, and stayed some days with me at Vulcano, has undertaken the task of describing that interesting event and the subsequent phenomena. He has very kindly forwarded me specimens of the ejectamenta, and to him I must express my thanks. He being already well acquainted with the products of that volcano, his observations will be of considerable value when published.

The first specimen submitted to me is that of the so-called bombs, common in other eruptions that have taken place from the present active crater of Vulcano. It is undoubtedly the *essential* ejectamenta, although included in the paste is much fragmentary *accessory* material. These so-called bombs are irregular polygonal masses of an obsidian-like material on the outside; the surfaces are traversed by a number of clefts or fissures V-shaped in section, which at their bottom and the deeper parts of their sides are seen to be composed of a spongy glass or even pumice. Their mode of formation is no doubt as follows:—The glassy magma from former loss of heat has become so viscous that the escape of vapours from the underlying magma is arrested until the tension rises, and the superincumbent pasty, almost solid, mass is broken up and ejected. This ejection has been preceded by some expansion and cracking, together with some cooling along the cracks, so that the blocks have partly consolidated as pumiceous obsidian, but when relieved from these conditions by ejection, the hotter material

within each block expands, due to the liberation, as vapour, of the dissolved H_2O, and the formation of a vesicular structure, which may progress to such a point as to constitute a true pumice. This is accompanied by fissuring of the external hardened surface, just as the expansion of dough splits open the crust, as the air-bubbles expand before and after the loaf is in the oven—in fact, we could not adopt a better term to define this structure than *bread-crust structure*. These fissures often divide crystals, pieces of included rock, &c., showing that little plasticity was left on the surface when this expansion took place. In fact, the conditions necessary are that the glass be sufficiently cold to break with a strain or blow applied sharply, but to bend when the force employed is gradual in its action, such as may be seen well in all vitreous substances. If we warm a stick of sealing-wax, hardened Canada balsam, &c., we may gently bend it to any form, but if our attempt is too quick, the stick breaks. In these bombs many of the surfaces appear to have first bulged and then broken. As these are ejected, and consist of a hard crust and soft interior, I suppose we must use that unfortunate term bomb, though they are rarely round and certainly do not strike one as resembling as much a bomb as do those masses found on the surface of lava-streams.

The colour is buffish-gray, the surface somewhat glistening and scattered over by the exposed broken surfaces (split by the division fractures between the contiguous blocks) of a dark green mineral, chiefly pyroxene, glassy crystals of feldspar, smaller black metallic lustred grains of magnetite, more rarely typical grains of olivine, quartz, and pyrites. There are also very many grains of different sizes of a darker-coloured fine-grained rock which incloses many of the augites, feldspars, olivines. Microscopically, the vesicular structure is seen to extend, though becoming less marked, to within (in the specimen examined) less than a millimetre of the surface, though in larger blocks from other eruptions preserved in my collection this may attain 2 centimetres or more. The crystals of pyroxene are usually well formed, though often broken. They include, wholly or partly, large, rather irregular magnetites, and in some cases are surrounded by wreaths of either sanidine or, more commonly, triclinic feldspar, probably labradorite. Where included in foreign rock-fragments, this latter is seen to be composed of a network of magnetite, augite, and feldspar microliths, and is often much altered. The feldspars are principally sanidines which may attain half a centimetre long; they are very dirty from inclusions, and somewhat rounded. There are also groups of labradorite crystals, and another triclinic feldspar in which the striations are remarkably close and fine. In some cases a triclinic feldspar seems to be intergrown with the sanidine. Of the latter mineral there are many microcrystals and microliths. Here and there are to be met with a few ill-formed crystals of dark-green amphibole.

What part of these minerals belong to the essential magma, and what are simply imperfectly fused out of the surrounding rock, it is extremely difficult to determine, and chemical analysis of the rock would be obviously useless, on account of the numerous inclusions of other rock-fragments. The association of such basic minerals with a distinctly acid rock would be very remarkable, were it not for the distinct origin of them by inclusion of accessory materials. The eruptive rocks of this island range from a very rich olivine basalt through a dolerite to the typical obsidians and spherulites. There is little doubt that these included minerals are the churned-up fragments in the crater apex which almost certainly cuts through those older rocks, and even part of the present active cone of Vulcano is composed of dolerite.

That these bombs are the primary ejectamenta in this eruption there is no doubt, on account of their freshness and the sharp uneroded angles and edges, as observed by Signor Platania, together with the absence of any solfatarizing. The specimen examined was ejected during the month of August, probably early in that month.

The next specimen is dated August 18, and consists of coarse sand or fine lapilli, about the size of a mustard-seed, with a little fine gray ash. This I made into an artificial breccia, and cut sections of it. It is composed of broken fragments of dolerite and glassy rocks, both often solfatarized, with chips of pyroxene, magnetite, &c., and, no doubt, is chiefly *accessory* ejectamenta derived from the crumbling sides of the crater being churned, ground up, and ejected.

Next is a fine ash of light gray colour, ejected on August 26, which is, in great part, also composed of similar materials to the last, with an abundance of very minute microliths, many of a dark-green colour, and therefore probably pyroxene or amphibole, though they remain dark between crossed nicols, from their great minuteness. I have observed no trace of tridymite found in such abundance in the ash of one of the recent eruptions of Vulcano. This we should expect to be formed at a later date, when the more tranquil vapours, escaping through the material at the crater bottom, would allow of their deposition.

From the description of the eruption by Mr. Narlian that was given in my paper on this subject at the British Association meeting this year, and reproduced in the *Times* and other newspapers, from the examination of the eruptive products, and from the state of the volcano previous to its last eruption (see my paper, "The Islands of Vulcano and Stromboli," NATURE, vol. xxxviii. p. 13) taken together with what we learn from the ejectamenta, we may obtain a fair idea of the eruptive process in this case. The chimney of the volcano was, no doubt, filled by an acid magma, which, perhaps, after the last eruption, was of much higher temperature, and in which fragments of other rocks from the crater and chimney sides had been churned up and partially fused. The temperature and liquidity seem to have been low, as the olivines and augites, although they have apparently been fused out of their original matrix, especially the latter, retain most perfectly their crystalline angles, and no chemical fluxing or reaction seems to have occurred between the basic minerals and the surrounding acid magma. Also, the occurrence of pyrites points in a similar manner to the same physical state. The choking of the crater after the former eruption, together with the gradual cooling of the upper part of the magma column during the intermediate solfataric stage of the volcano, would result in a gradually increasing obstacle to the boiling-off of the H_2O dissolved by the magma lower down. Two processes would therefore be going on, viz. increased superincumbent pressure, and augmenting tension of the part of the subjacent magma within reach of water-supply. The latter must obviously, after a certain time, increase in a greater ratio than the former, until the plug is blown asunder.

This plug in great part would consist of the magma with its inclusions reduced to that critical state between a liquid and solid, as seen in vitreous bodies. When this is broken up by the sudden impulse of the expansion of the subjacent aquiferous magma, it would split into fragments; and, these immediately cooling on their surface by the molecular formation and escape of vapour near that surface, cooling and solidification would result, but before this extended far in, the hotter interior would undergo frothing, and so bend, crack, and fissure the nearly hard coating, producing in this manner the bread-crust structure. These blocks seem from Mr. Narlian's account, to have fallen nearly red hot, as his children's feet were burnt, and part of the house where they fell was burnt. After the first explosion, a series of feebler explosions took place, and, I believe, are still continuing with diminished force, just as is seen

in boiling up an extremely thick syrup. Add to this the crumbling in of the crater-sides, their pulverization and ejection, and we have the picture of a typical paroxysmal eruption, tending towards an explosive one, of an obsidian volcano. H. J. JOHNSTON-LAVIS.

Naples, November 3.

Since writing the above, I have received the following letter from Mr. Narlian, which will form a fitting appendix to his former one read at the British Association, and published in the *Times* and elsewhere.

"*Lipari*, *Italy*, *November* 3, 1888.

"MY DEAR DR. JOHNSTON-LAVIS,—I have your kind note, for which I thank you. Our crater (*i.e.* Vulcano) is still in a very active condition. The eruptions succeed each other nearly every minute or two. Columns of thick black ashes are ejected to heights that cannot be less than 15,000 feet. The stones, red hot, are also thrown out in immense quantities and to great heights. Sometimes these eruptions are accompanied by loud detonations, which are indistinguishable from those of a gun, only they are so overpoweringly loud that at Lipari they are heard as if a piece of 100 tons had gone off near at hand. Till now there is no lava, and we hope there will not be any.

"I observe a difference in the ejected matter: in the beginning of the eruption they were stones, in time they began to show a burned calcined appearance, became quite black and friable by the action of the fire, and now they are nearly pumice of a dark and rough kind.

"I shall be glad to send you some few specimens by the first boat for Naples.

"I am, dear Sir,

"Yours faithfully,

"A. E. NARLIAN."

This prolonged activity is a most interesting phenomenon, and two explanations are open to us—viz. either the supply of igneous magma has increased, and the volcano is passing from the solfataric stage to a strombolian or Vesuvian phase, or the supply of dissolved H_2O in the magma extends to great depths, or is derived from a very large mass of magma. The change in the ejectamenta would rather point to the latter; as if, the first boiled paste being ejected, the more aquiferous paste from greater depths was undergoing discharge of its vapour. This may possibly be followed by the eventual outpour of lava, indicating the arrival at the surface of still deeper magma, comparatively poor in dissolved H_2O, so that the view of an obsidian stream may be in store for us before long—an event of considerable importance to vulcanological science. H. J. JOHNSTON-LAVIS.

NOTES.

WE lately noted that Mr. J. F. Duthie, Director of the Botanical Department, Northern India, had accompanied the recent military expedition to the Black Mountain country. The Black Mountain forms the northern boundary of the district of Hazara, which forms a long narrow valley, bounded on the west by Cashmir. Extending far into the heart of the outer Himalayan range, it is shut in on either side by mountains, rising to 17,000 feet. The flora is almost wholly unknown. But the time of year was unfavourable for botanical collecting, and Mr. Duthie writes to Kew: "I did not manage to find much of botanical interest on the Black Mountain; excepting the fine bits of forest, composed of *Abies Webbiana* and *Pinus excelsa* on the crests of the mountain, the country is barren in the extreme."

THE Kew Museum has lately received a choice collection of interesting objects from Corea, collected and brought home by Mr. T. Watters, who was Acting Consul in that country from January 1887 to June last. The specimens in question, which consist of hand-screens, fans, &c., made of paper from the paper mulberry (*Broussonetia papyrifera*, Vent.), together with samples of the paper itself, sun-blinds made of split bamboo, &c., illustrate in a remarkable degree the extreme neatness and accuracy of the Coreans in their handicrafts. The following are some of the specimens received and now exhibited in the Kew Museum. A series of different qualities of paper, all made from the bark of the paper mulberry. These comprise plain white or cream-coloured papers of various degrees of finish, used for drawing, writing, packing, &c.; also coloured papers such as are used by the people for writing birthday missives upon. It would seem that the Coreans, like the Japanese, use paper very extensively for a great variety of purposes. Thus, for fans, the handles of which are delicately ornamented, as well as for hand-screens, tobacco-pouches, coverings for hats in wet weather, paper is equally applicable; for the latter purposes, however, it is steeped in oil, which makes it thoroughly waterproof. The hand-screens are made by first forming a foundation of thin strips of split bamboo radiating from the handle, which is afterwards covered so completely on both sides with a thin paper film and varnished that a strong and durable article is the result. Some of the hand-screens presented by Mr. Watters to the Kew Museum were given to him by the King, and are of much finer workmanship than those that are purchasable. The oil-steeped paper tobacco-pouches and hat-coverings are a close imitation of oilskin; the latter, which when opened is cone- or tent-shaped, is used by all classes except the peasantry, even including the soldiers. The Corean boy's kite, which is also made of *Broussonetia* paper, consists of a piece of paper about a foot square with a circular hole in the middle, kept in form by thin strips of bamboo; a thin string is attached to each corner and brought together and connected to a single string, which is wound upon a wooden windlass. The perfection of splitting bamboo into thread-like strips seems to be divided equally between the Chinese and the Coreans, judging from a remarkably fine example of a blind which forms one of the exhibits. These very fine blinds are said to be used only by high mandarins, and the coarser kinds by the lower classes. Another illustration of very fine work is in the utilization of split rattans in the manufacture of articles of clothing, an undershirt and cuffs of very open ornamental workmanship being made entirely from this material, which is both soft and pliable. These shirts are said to be used next the skin in hot weather to prevent the oute shirt adhering to the body.

MR. J. S. JAMESON, of the Emin Pasha Relief Expedition, who died of fever at Bangala Station, on August 17 last, had accumulated a number of carefully-selected trophies and objects of natural history. These objects have been brought together at 166 Piccadilly, and arranged by Mr. Rowland Ward, so that they may be accessible to naturalists, and to his friends, who have been invited to view them to-day.

THE Russian Geographical Society has just published an "Instruction for Observations upon Shifting Sand Regions." The paper was carefully prepared by a Committee of persons thoroughly acquainted with the subject, and might with advantage be translated and communicated to other Geographical Societies.

AN important addition to school laboratories has just been completed at Eastbourne College, where the science teaching is undergoing great development. The laboratory, which has just been built there, affords working accommodation for twenty-four students, and has been thoroughly well fitted. The working

benches are ranged down each side of the length of the room, and are all fitted with gas and water; and ample storage room is provided by four capital cupboard-cases. An excellent lecture-table occupies the usual position; the sand-bath and still are of copper, and heated by Fletcher's burners. There is also a convenient master's room, which, when finished, will be very complete.

PROF. H. G. SEELEY, F.R.S., is about to deliver a course of lectures on the practical study of the geology of the country round London. This course is given at the request of students of the London Geological Field Class; and information concerning the lectures may be obtained from Mr. William Dunn, 21 King William Street, Strand, W.C.

THE Penny Science Lectures at the Royal Victoria Hall for the month of December will be as follows:—December 4, on "Nature's Hot Springs," by Dr. S. Rideal; December 11, on "Limestone Rocks and their History," by Mr. E. Wethered. The series will begin again on January 22, 1889.

AT a *conversazione*, given by the Oxford University Junior Scientific Club, on Friday, November 23, in the University Museum, Prof. Milnes Marshall, of the Owens College, delivered a lecture on "Animal Pedigrees," which was highly appreciated by a numerous company of members of the University and their friends. Later in the evening Colonel Gouraud introduced and explained the new Edison phonograph. The members of the Club further entertained their guests by varied scientific exhibits and demonstrations, while the band of the 60th Royal Rifles enlivened the proceedings with music.

THE Duchess of Albany has consented to become Patroness of the Sanitary Institute.

A GIGANTIC stalactite cave has been discovered near Rübeland, in the Harz Mountains, surpassing the neighbouring Bauman's Cave in size and beauty. Some excellent photographs of different parts of the cave were taken by Dr. Max Müller, of the Brunswick Technical High School, by means of the electric light. These photographs are shortly to be published, accompanied by explanatory notes by Prof. Kloss, of Brunswick. The cave is to be lighted by electricity, and opened to the general public next year, after precautions have been taken to keep it in its present perfect state.

DURING the last summer Dr. Otto Zacharias examined carefully the crater "Maare" (lakes) of the volcanic Eifel. They are inhabited by numerous species of Copepoda, Daphnidæ, Radiolaria, Rotifers, water mites, and insect larvæ. The largest of the "Maare," the Laacher See, which measures about seven miles in circumference, contains a special fauna. Besides this lake, Dr. Zacharias examined four others: the Pulvermaar, Holzmaar, Gemündener Maar, and Schalkenmehren Maar.

AT the meeting of the Royal Meteorological Society on November 21, Dr. A. Riggenbach, of Basle, read an interesting paper on a method of photographing cirrus clouds. Great difficulty is experienced in obtaining photographs of cirrus clouds, the reason being that the blue light of the sky acts with nearly the same actinic energy as the white light of the clouds on the sensitive silver salts of the plate. What is wanted is that this blue light of the sky should be dulled, the light of the clouds being left unaffected, and this can be done by means of the analyzer of a polarizing apparatus. The light from the blue sky is partly polarized, and to the largest extent at the points which are situated 90° from the sun; the plane of polarization passing through the points looked at, the sun, and the eye of the observer. On the other hand, the light coming from a cloud is only polarized to a slight extent. Having spoken of what can be done by the use of a Nicol's prism, Dr. Riggenbach went on to say that we might substitute for a Nicol's prism a dark mirror, a painter's mirror, or, best of all, a plate of obsidian. If such a plate be held so that the plane which passes through the cloud, its reflected image, and the eye, is normal to the line from the observer to the sun, the mirror extinguishes the polarized light from the sky almost completely, and the reflected image of the cloud comes out sharp on a dark background. If such an obsidian plate be fixed before the lens of a photographic camera, so that its plane is inclined at an angle of 33° to the optical axis of the lens, and the camera be placed so that the sun's rays shine perpendicularly on one of its sides, we then turn the whole apparatus round, in the direction in which the sun lies, as an axis, until a cirrus cloud is visible in the camera. If a sensitized plate be inserted, a picture of the cloud can be produced under the most favourable conditions possible. A still simpler mode of obtaining such cloud pictures is to use the surface of a lake as a polarizing mirror. The best clouds for such a purpose are those at sunrise or sunset, at an altitude of about 37°, and in an azimuth either greater or less than that of the sun by 90°.

THE North Atlantic Pilot Chart for November states that the most noteworthy disturbance during October was a West Indian hurricane which developed near Yucatan on the 9th, and reached the south coast of Long Island on the 12th. The tracks of all the depressions moving eastward from the American coast during the first half of the month lay well to the northward of the normal path until reaching the 55th parallel. This is very interesting in connection with the persistence with which an energetic area of high barometer lingered over the middle of the Atlantic, and affords a good illustration of the tendency of areas of low pressure to avoid those of high. Only one iceberg, near Belle Isle, was reported.

WE have received the Report of the Meteorological Service of the Dominion of Canada for the year 1885, which shows continual progress and improvement in the various departments. In addition to the Annual Reports, containing the results for numerous stations, a Monthly Review is published giving a general *résumé* of the weather throughout the Dominion, and an analysis of the daily forecasts and storm warnings. The weather signals carried on the railway cars are much appreciated, both by the farming community and the general public. New stations are established in the more remote districts as opportunities offer, and many valuable observations are also obtained along the line of the Canadian Pacific Railway, in regions where it is difficult to get observers other than the station officials.

Two fine series of salts of two new platinum bases containing sulphur and organic radicles have been prepared by the Swedish Professor Blomstrand and his assistants, of Lund. They will form a striking addition to the now large number of these remarkable platinum compounds, which have been obtained since the preparation of the first of their class, the well-known green salt of Magnus, in 1828. When a solution of potassium platinous chloride, K_2PtCl_4, is shaken with two molecular equivalents of ethyl sulphide $(C_2H_5)_2S$, a quantitative precipitation of a yellow chloride, of the composition $Pt^{S(C_2H_5)_2\,.\,S(C_2H_5)_2Cl}_{Cl}$, occurs. On treating this somewhat complex substance suspended in water with another two equivalents of ethyl sulphide, the whole eventually dissolves, with the exception of a small quantity of an oily substance, which appears to be formed as a secondary product. On allowing the separated clear liquid to stand, it gradually deposits crystal crusts of greenish-yellow monoclinic tables of the chloride of the first new base, $Pt^{S(C_2H_5)_2Cl}_{S(C_2H_5)_2Cl}$. In a similar manner, Prof. Blomstrand has obtained the bromide, $Pt[S(C_2H_5)_2Br]_2$, which crystallizes in reddish-yellow monoclinic prisms; and the iodide, which resembles the bromide very closely, but forms beautiful dark-red monoclinic crystals of considerable size. In addition to these well-defined halogen salts, the nitrite

was obtained in large colourless rhombic crystals; the sulphate, $Pt[S(C_2H_5)_2]_2SO_4 + 7H_2O$, in exceptionally large crystals exhibiting a great number of faces; and also the nitrate in very soluble crystals. The halogen salts of the group are readily transformed into the more stable platinic compounds, which are found to be much more difficultly soluble. Thus the chloride, $Cl_2Pt[S(C_2H_5)_2Cl]_2$, was obtained in the form of yellow tables and prisms belonging to the triclinic system. The bromide forms red monoclinic prisms, and the iodide, perhaps the prettiest salt of the whole series, crystallizes from chloroform in dichroic prisms, which appear dark red by transmitted, and dark blue by reflected, light. The second series of salts are precisely analogous, but contain the radicle methyl instead of ethyl. It is interesting to note that Prof. Blomstrand was successful in isolating the base of the second series itself, $Pt[S(CH_3)_2]_2(OH)_2$, as a yellow, strongly alkaline liquid. Between the two series, an interesting mixed sulphine-chloride was obtained, containing both ethyl and methyl, $Pt\genfrac{}{}{0pt}{}{S(C_2H_5)_2Cl}{S(CH_3)_2Cl}$, by the addition of two equivalents of methyl sulphide to the yellow chloride first mentioned above. It will be readily seen that the work thus briefly reviewed forms a most valuable contribution to our knowledge of the platinum bases.

A LIST of the writings of Dr. Asa Gray, chronologically arranged, with an index, has been printed as an appendix to vol. xxxvi. of the *American Journal of Science*, and is also published separately. The compiler has done his work with great care.

IN an interesting paper on "Musical Sands," Mr. C. Carus-Wilson has discussed the cause of the remarkable sonorous properties exhibited by the sands of various localities, a subject which was referred to in this journal on August 30 and September 27 of the present year. Mr. Carus-Wilson gives the details of numerous experiments. Some of them are of a very ingenious character, which lead him to the conclusion that the vibration of the individual sand-grains is brought about by friction, and that it is the cumulative effect of numerous vibrating particles of the same size that becomes audible. This conclusion differs in some respects from the theories which have been put forward by some other investigators of these very curious phenomena.

THE first part of a useful "Introduction to Entomology," by J. H. Comstock, has been published at Ithaca, U.S.A. The groups of insects have been fully characterized, so that their relative affinities may be learned; and much space has been given to accounts of the habits and transformations of the forms described. The work contains many original illustrations.

A LITTLE book, by Mr. W. Mawer, containing a brief account of the life and discoveries of Darwin, has just been issued by Messrs. Swan Sonnenschein and Co. The volume is likely to be of interest to young people, for whom it has been specially written.

IN the Administration Report of the Madras Government Central Museum for the year 1887-88, Mr. Thurston, the Superintendent, speaks of two tours which he made during the year on behalf of the Museum, viz. to Tuticorin and the Nílgiris. At the former place great assistance was rendered by Captain Phipps, Port Officer, in placing boats and divers at his disposal. Large collections, illustrative of the marine fauna, were made, mainly through the medium of native divers, who displayed no little skill, and some of the specimens, *e.g.* the entire collection of Sponges and Echinoderms, have been sent to the British Museum (Natural History), for investigation and report. The results of this tour will be published after Mr. Thurston has made a further tour of the Gulf of Manaar. During his tour on the Nílgiris a large area of both the plateau and slopes was explored, and large collections of birds, reptiles, butterflies, &c., were made, but as he only returned to Madras a few days before the termination of the official year, he reserves a list for his next annual report.

THE current number of the *Asiatic Quarterly Review* contains an article by Captain A. C. Yate on the Shan States, in which reference is made to the ethnology of the obscure region bounded on the west by Burmah, on the north and north-east by China, on the east by Tonquin, and on the south by Siam and the Karennee. Of the Shans he has a very low opinion: he describes them as sordid and lazy, they live in extreme poverty, they are not brave, and their foot is yet barely on the lowest rung of the ladder of civilization. Still, they are somewhat ahead of the tribes around them. They have a literature: Captain Yate says it lies about dirty and uncared for in pagodas, priests' houses, and travellers' rest-houses. Amongst the other tribes inhabiting the same region are the Palaungs, the Red and White Karens, Kakyens or Kachins, Dunoos, Laos, Was, Kaws, Chins, Yíns or Yeíns, Yindalaings, Padaungs, Taungthus, Müsüs, and Kakins. All these are believed to speak their own dialects, but none of them have a written language. The Palaungs, Kachins, and Laos are the more important of these. The Kachins are extending all over the region, and are hated and feared by the Shans. They worship or propitiate certain evil forces in Nature which they call "nats." Captain Yate gives some curious details in regard to this and other tribes, but his aim is rather to describe what they are as he saw them, than to discuss the ethnological problems connected with this region and its races and fragments of all but extinct peoples.

IN a paper in the current number of the Journal of the Anthropological Institute, Mr. J. Allen Brown states, on the authority of Mr. Carlyle, late of the Archæological Survey of India, that some few of the rudest aboriginal tribes of the wildest central parts of India still practise a modified and partial sort of tattooing, but only with deep blue or other dark or grey colour, never with red. Hindus use red and white, and sometimes yellow colours superficially, without incisions, which will wash off, as religious sectarial caste marks on their foreheads. These are the only instances, so far as Mr. Brown can learn, where such pigments are now used either for embellishment or religous symbols in India.

WE have received the second part of vol. iii. of the Proceedings of the Linnean Society of New South Wales. The following are among the contents: on additional evidence of the genus *Ichthyosaurus* in the Mesozoic rocks ("Rolling Downs Formation") of North-Eastern Australia, by R. Etheridge, Jun. (Plate vii.); on additional evidence of the occurrence of *Plesiosaurus* in the Mesozoic rocks of Queensland, by R. Etheridge, Jun. (Plate viii.); description of a new *Tripterygium* from Port Jackson, by E. P. Ramsay and J. D. Ogilby; notes on the Mueller Glacier, New Zealand, by Captain F. W. Hutton (Plates ix. and x.); the insects of King's Sound and its vicinity (Part 1), by William Macleay; Australian indigenous plants providing human foods and food-adjuncts, by J. H. Maiden; geographical notes in Malaysia and Asia, by the Rev. J. E. Tenison-Woods; Diptera of Australia (Part 2, the Sciaridæ), by F. A. A. Skuse (Plate xi.); note on sympathy and foster-parentage among birds, by E. G. W. Palmer; on some new and rare Hydroida in the Australian Museum Collection, by W. M. Bale (Plates xii.–xxi.); notes on Australian Coleoptera, with descriptions of new species, by the Rev. T. Blackburn; the development and structure of the pineal eye in *Hinulia* and *Grammatophora*, by W. J. McKay (Plates xxii.–xxiv.).

IN his note on sympathy and foster-parentage among birds, Mr. Palmer tells a curious story of a wood-duck and a hen.

"Some time ago," he says, "a boy brought in an egg found near a waterhole, which was placed with other eggs under a sitting hen, and in due course hatched out a wood-duck. The wood-duck was reared among a clutch of chickens, was as well tended as her other chicks by the mother hen, and reached adult age. On one occasion a hen brought out a brood of chickens, and the wood-duck kept in close companionship with the hen and chicks for several days, until the hen took umbrage at the duck's constant attendance, and several fights between the hen and duck ensued. Eventually the duck drove away the hen, and took sole charge of the chickens throughout the day, the hen following round disconsolately till night-fall each day, when the duck surrendered her charge, allowing the mother to brood over them at night, but again taking charge of them in the morning. This continued till the chickens were able to take care of themselves."

THE writer of the article on "The Opening of the Pasteur Institute" (NATURE, November 22), informs us that by an oversight a misprint occurs on p. 74, in the first line of the second paragraph. Class *C.* should read Class *A*.

THE additions to the Zoological Society's Gardens during the past week include a Black-eared Marmoset (*Hapale penicillata*) from South-East Brazil, presented by Miss B. Pollock; a Malbrouck Monkey (*Cercopithecus cynosurus*) from West Africa, presented by Mr. David Baumann; a —— Toad (*Bufo* ——) from California, presented by Mr. D. E. Cardinall; a North American Turkey (*Meleagris gallo-pavo*) from North America, presented by Mr. F. J. Coleridge Boles; a Tawny Owl (*Syrnium aluco*), European, deposited.

OUR ASTRONOMICAL COLUMN.

COMET 1888 *e* (BARNARD, SEPTEMBER 2).—Dr. L. Becker, who has recently computed elements for this comet by the method of variation of the distances, finds (*Dun Echt Circular*, No. 164) that the most probable orbit is hyperbolic in character, the residuals for the intermediate observations being much larger for the most suitable parabola than for the hyperbolic orbit.

The elements are as follow :—

$$T = 1889 \text{ January } 29\cdot90453 \text{ G.M.T.}$$

$$\left.\begin{aligned} \pi - \Omega &= 339^\circ\ 54'\ 32''\cdot1 \\ \Omega &= 357\ \ 15\ \ 59\cdot1 \\ \iota &= 166\ \ 22\ \ 24\cdot3 \end{aligned}\right\} \text{Mean Eq. } 1888\cdot0.$$

$$\log q = 0\cdot2595204$$
$$\log e = 0\cdot0135800$$

Ephemeris for Greenwich Midnight.

1888.	R.A. h. m. s.	Decl. ° ′	Log Δ.	Log *r*.	Brightness.
Nov. 29	2 28 2	5 57·3 S.	0·0501	0·2971	12·1
Dec. 1	2 15 18	6 21·0			
3	2 3 9	6 41·4	0·0669	0·2928	11·4
5	1 51 40	6 58·4			
7	1 40 50	7 12·2	0·0887	0·2887	10·5
9	1 30 42	7 23·2			
11	1 21 15	7 31·5	0·1131	0·2847	9·6
13	1 12 29	7 37·5			
15	1 4 21	7 41·2 S.	0·1390	0·2810	8·7

The brightness on September 2 has been taken as unity.

Dr. Berberich has, however, computed parabolic elements using an observation made at Karlsruhe on October 28, the ephemeris from which satisfies well an observation obtained at Rome as recently as November 7.

According to Dr. Becker's ephemeris, the comet will pass within 1½′ of a bright nebula, 100 ♅ I Ceti, a little before midnight on December 10, and as the head of the comet is of very considerable size, the nebula will be completely involved in it. The moon will be near setting, so that, though the comet will be low, about 75° Z. D., spectroscopic observations might be obtained if the night were clear. Dr. Berberich's elements would place the transit some three hours later, when the comet would have set to English observers, but makes the transit nearly a central one.

COMETS FAYE AND BARNARD, OCTOBER 30.—The following ephemerides for these objects for Berlin midnight are by Drs. Lamp and Spitaler respectively (*Astr. Nach.*, No. 2867) :—

	Comet 1888 *d* (Faye).		Comet 1888 *f* (Barnard, Oct. 30).	
1888.	R.A. h. m. s	Decl. ° ′	R.A. h. m. s.	Decl. ° ′
Dec. 1	8 14 34	2 29·2 N.	10 19 27	8 50·8 S.
3	8 14 36	2 12·8	10 20 47	8 16·9
5	8 14 30	1 57·2	10 21 59	7 41·5
7	8 14 15	1 42·6	10 23 4	7 4·4
9	8 13 52	1 28·9	10 24 0	6 25·8
11	8 13 21	1 16·2	10 24 50	5 45·8
13	8 12 42	1 4·5	10 25 32	5 4·2
15	8 11 55	0 53·9	10 26 4	4 20·7
17	8 11 1	0 44·4	10 26 28	3 35·5
19	8 10 1	0 36·1 N.	10 26 45	2 48·8 S.

The brightness on December 19 of Faye's comet is 1·8 that of the brightness at discovery; of Barnard's, 0·9: Both comets change but slowly in brightness, as the distance from the earth is diminishing, whilst the distance from the sun is increasing.

THE SATELLITE OF NEPTUNE.—Mr. A. Marth pointed out in the *Monthly Notices* (vol. xlvi. p. 506), some two years ago, that the values for the inclination of the orbit of the satellite of Neptune and its ascending node, as deduced from the observations obtained in Malta in the years 1852 and 1864 by Lassell and Marth, and again at the Washington Naval Observatory from 1874 to 1884, show a well-marked, progressive, and regular change. Referring these values to the plane of the orbit of the planet, they are as follows :—

Date.	*n.* °	*i* (motion considered direct). °
1852	176·20	148·33
1864	180·41	146·19
1874	182·59	144·04
1883	184·31	142·38

Mr. Marth offered no theory by which to account for this change, but begged for continued observations. Prof. Asaph Hall also has more recently urged the necessity for further observation, and by fresh observers, avowing at the same time his suspicion that these changes are due to systematic errors in the observations. But M. Tisserand, in a late communication to the Academy of Sciences of Paris, shows that the changes can easily be explained by the theory of a slight flattening of the surface of Neptune. In this case the angle between the plane of the planet's equator and that of the orbit of the satellite will be constant, and the pole of the orbit will revolve in a small circle round the pole of the planet, a complete revolution taking more than 500 years. The inclination of the orbit of the satellite will be considerable, probably greater than 20°; but the flattening of the surface of Neptune can only be slight, too small to be detected by direct measurement. Further observations may enable the amount of the inclination to be more exactly determined, and, at the same time, will show whether the changes in question are due or not to this one cause alone.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 *DECEMBER* 2–8.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on December 2

Sun rises, 7h. 48m.; souths, 11h. 49m. 49·0s.; sets, 15h. 51m.: right asc. on meridian, 16h. 36·8m.; decl. 22° 5′ S. Sidereal Time at Sunset, 20h. 39m.

Moon (New on December 3, 10h.) rises, 6h. 3m.; souths, 10h. 56m.; sets, 15h. 39m.: right asc. on meridian, 15h. 42·7m.; decl. 15° 23′ S.

GEOGRAPHICAL NOTES.

At the usual meeting of the Royal Geographical Society on Monday, Mr. J. Thomson read before a large audience a paper on "A Journey to the Atlas Mountains." He gave a most interesting account of the scenes visited, in the course of his trip, by himself and his companion, Mr. Harold Crichton-Browne. Describing some of the practical results, he said they had ascended and crossed the Atlas Chain in no fewer than six different places besides making various subsidiary trips into the lower ranges. A large series of barometric and boiling-point observations have been taken, which would assist in forming a more accurate idea of the general elevation of the range. Several glens had been explored, and the head-waters of some important streams had been mapped out. New and important light had been thrown upon the geological structure of the mountains. A small collection of plants from the higher altitudes had been made, and finally a series of photographs (which were exhibited) of the mountains, the inhabitants, and their houses have been obtained. He had reached an altitude in the mountains 1300 or 1500 feet higher than any other traveller.

The December meeting of the Royal Geographical Society will be held on Monday, the 17th, at the University of London, instead of Monday, the 10th, as announced in the sessional programme. Colonel R. G. Woodthorpe will read a paper on explorations on the Chindwin River, Upper Burmah.

The Russian Expedition for the exploration of Tibet, organized by the late General Prjevalsky, is, notwithstanding the death of the famous explorer, to be despatched on its mission. This announcement was made by M. Semenow, the Vice-President of the Russian Geographical Society, at a meeting held by the Society in honour of General Prjevalsky.

THE RENAISSANCE OF BRITISH MINERALOGY.[1]

An ideal Presidential address should treat, not of a special point in the science of interest to a section only of the Society, but of the science in its broader aspects ; and the simplest permanent arrangement of this kind is that which makes it deal with the progress of the Society or of the science during the interval which has elapsed since the delivery of the next preceding address.

But in the case of our own Society we labour under special disadvantages, whether the address is to be on a specific subject or on the progress of the science. Not only is the Society small, but the number of its members able to devote any large part of their time to pure mineralogy is far smaller still. Hence if a set address were expected from the President we should be unnecessarily limited in our selection for that office. Many of our ablest members, men who would make the best of Presidents, men of wide culture and extensive general knowledge, men endowed with ideas and the power of expressing them, men who would bring to us a large experience obtained on the executive of other and larger Societies, though willing, nay anxious, to help us in the management of the affairs of the Society, would be prevented from giving us their services in the chair, owing to the sheer impossibility of devoting the requisite time and thought to the preparation of a purely mineralogical address such as they would consider worthy at once of the Society and of their own reputation.

Again, the number of our London meetings has been up to the present only three a year, and, as far as we can see, it is not yet desirable to increase their frequency. To set aside annually one-third, or even one-fourth, of the time of the Society for consideration of the views of the President, or of the progress and past work of the Society, would seem to be wanting in regard for proportion. A few minutes spent by the members in turning over the pages of the *Magazine* will give a better idea of the work of the Society, and be at the same time more exhilarating, than any summary a President can make. A report by the Council on the finance and general business, as brief as it can be made, seems to me sufficient for all reasonable purposes, and least wasteful of the time of the members and officers.

I have referred to the *Magazine*, and have said that a good idea of the work of the Society may be obtained in a few minutes by turning over the pages of one of its volumes. It may be cast in our teeth that the volume is small, but we can proudly and truly retort that few volumes of the same size furnish so vast an amount of heavy reading. The density, indeed, is prodigious—not that of lead, but of gold, refined gold. The volume is intended for transmission to all posterity, and not as a mere addition to the ephemeral literature and scientific gossip of a too prolific century. The present generation, by its careful use of the volume, will doubtless help it to reach its destination.

Bulky publications are, indeed, matters for shame rather than pride : they are the immediate ruin of a small Society, a perennial burden to librarians, and, as their contents are never completely indexed, a terror to subsequent investigators. The Ancients not unwisely refrained from the invention of printing ; they recognized that their duty to themselves was to read only what was worth the vast labour of transcription, and that their duty to posterity was to transmit to it only their masterpieces ; when even these became burdensome, an incendiary, doubtless a librarian, quickly reduced their volume. But for us Moderns the cost of multiplication of copies has become so small that everything, good or bad, is printed and preserved ; and it becomes necessary to spend the greater part of one's life in the preparation and study of indexes rather than of the literature itself. It would be an immense boon to mankind if some impartial and perfect tribunal could be empowered to do on the large scale what the curate and barber did so satisfactorily with Don Quixote's books on the small scale—distinguish the worthy from the worthless, and relentlessly annihilate that which ought not to cumber our shelves or demand even a passing glance.

I have said that the number of our members is small. I am not sure that it would be politic as yet to increase it. Members who have a living interest in mineralogy are most valuable, and of such we cannot have too many ; but mere subscribers of paltry gold would eventually be a source of weakness. After encouraging the Society to extravagant expenditure, they would fall away and leave it in the lurch.

[1] Extracted from an address by Mr. Fletcher, the retiring President, at the annual meeting of the Mineralogical Society, October 30, 1888.

But is it necessary that the number of people in this country with a lively interest in mineralogy should remain so small? We have only to look abroad to see at once that the cause of this smallness of number is not inherent in the subject itself. In Germany, for instance, everyone—of course, with here and there a conspicuous exception—seems to be either a Professor of Mineralogy or a student of it. Periodical publications, at once voluminous and teeming with valuable results of scientific work, are there maintained. Somewhat more than a century ago, the study of minerals was everywhere popular, and received its share of attention from the cultured classes. Students thronged to Freiberg from all parts of the world to hang on Werner's lips.

There is one reason for this decline of general interest in mineralogy which I may mention in passing. In the good old days minerals were named and classified by help of simple external characters, and the facts of the science could be easily grasped without much preliminary training. Since then, the invention of crystallography and of the atomic theory, and the discoveries made in physical optics, have brought about a vast change in the treatment of the subject, and the mineralogy of to-day is even in its elements beyond the range of ordinary mortals. The pages of its text-books are sprinkled with wonderful formulæ designed by perverse chemists, and with unpronounceable hieroglyphics maliciously invented by cruel crystallographers.

But the chief reason for the decline of mineralogical study in our own country is that mineralogy has been almost completely excluded from our educational system. In the older Universities, it is true, mineralogy has been long represented by Professors, but, until lately at least, it has been allowed scarcely any weight in the examinations for a degree. The study of other branches of science has been encouraged, while that of mineralogy has been neglected and forgotten. One of the evils of the examination system is that all the available energy of our youth is concentrated wholly on subjects upon which stress is laid by a not omniscient Examining Board; most students, too, must almost necessarily take up subjects in which there is an opportunity of showing their comparative ability, and by a knowledge of which there is reasonable prospect of being able to gain a future livelihood.

Taught only as a subordinate and unimportant subject at the Universities, and not taught at all outside, pure mineralogy has been in great danger of becoming extinct in this country: a few years ago the capsizing of a coach or the bursting of a balloon might have been the end, and the British Professor or student of pure mineralogy have become a mere tradition.

The discovery of the transparency of thin rock-sections, and the important conclusions which may be arrived at from their microscopical examination, have now turned attention to mineralogy once more, and it seems likely that the knowledge of mineral characters requisite for petrographical work may at last lead to our mineralogical renaissance. Owing chiefly to the patience and perseverance of Prof. Lewis, there is now a certain amount of encouragement to mineralogical study at Cambridge; and if the renaissance is to be brought about, the example of Cambridge must be followed by the other Universities, and mineralogy be assigned a higher place in the examinational system.

Minerals are omnipresent. Is it unreasonable to ask that everyone should be taught their simple characters, and be shown how to recognize such minerals as are met with at every turn? The teaching would improve the capacity for observation, and give fresh interest to many a pleasant ramble—through the workings of a mine. And is not Prof. Ruskin in the right when he claims that a knowledge of the minerals, conveniently grouped as precious and ornamental, should form a part of every gentle education? More especially ought we not to insist upon such elementary teaching for the numerous officials sent out by the nation to the less explored regions of the world?

In the higher teaching of mineralogy, difficulties present themselves, but they might easily be lessened by division of labour; a preliminary training in the elements of mathematics, physics, chemistry, and crystallography being absolutely necessary to the manufacture of a mineralogist. The teaching of crystallography is generally relegated to the Professor of Mineralogy, and the subject regarded as a mineralogical difficulty; but this ought not to be the case. It is true that a mineralogist was the first to discover a relationship between the various crystallized forms of the same substance, and thus to institute a crystallographic science, which has since been found indispensable in mineralogical study. It is true that the mineralogist has been the originator of every advance in crystallographic knowledge. It is true that the mineralogist has in minerals ready-made crystallizations, which in their excellence and variety of form can rarely be imitated in the laboratory. But it is no more the province of a mineralogist to teach crystallography than it is to teach chemistry or the use of a delicate balance. He does teach it indeed, but that is merely because his pupils reach him imperfectly trained for the pursuance of his own subject.

Crystallography should be taught as a special subject; and a knowledge of it should be required not only of the mineralogist but of the chemist, and even of the physicist. Hitherto, at least, the chemists of this country have been too content either to leave the crystalline forms of their artificial products undetermined, or to impose the task of their determination on the already sufficiently occupied mineralogist. It seems obvious that in a satisfactory system of education every chemist should be taught how to measure and describe the crystalline characters of the products which it is his fate to call into existence. On various occasions expression has been given to this view, but the only chemist who has yet seen his way to act upon it is Prof. Henry Armstrong, who, I am happy to say, has introduced the subject into the educational course of the City and Guilds Technical Institute. I trust that before another generation passes away his excellent example will be followed throughout the country. A knowledge of the elements of crystallography, including the mechanics of crystal measurement, ought to be made a *sine quâ non* for a degree in chemistry at every University.

The measurement of the angles of a crystal, the determination of its symmetry, and the calculation of its form, are infinitely less difficult than is generally imagined: given a knowledge of elementary mathematics and the careful use of measuring instruments, the processes are in general extremely simple. The complexity of crystallographic calculation is only apparent, and is due to the existence of text-books: they are generally worse than useless. A voluminous work on crystal-calculation is usually an attempt to provide formulæ which shall enable a student to solve every possible problem by rule of thumb, without his needing to have the faintest idea of what he is really doing. Practically, anyone familiar with the processes of trigonometry can deduce from first principles the formula required for each special case as it occurs in less time than he can discover the rule in the ponderous tome invented for his mystification.

I am, of course, far from asserting that the teaching of crystallography presents no difficulties at all: what I do wish to insist upon is that the kind of crystallographic knowledge requisite for the chemist in his own work is such that it may fairly be demanded of every one of them: the higher flights may be abandoned to the specialist.

At the present time, when Professors of Crystallography are not yet called into existence, there is one step which ought to be at once taken, and which would make mineralogy more possible eventually to a large number of our students. Every student of practical physics is taught how to measure with a reflecting goniometer the angles of an artificial prism: he should further be taught the measurement of the angles of a simple crystal, and the deduction of its symmetry. In his optical studies especially, such a practical knowledge of crystalline symmetry would be a great help to him. The reflecting goniometer in one of the forms used for crystallographic work might well be an instrument in use in every physical laboratory, and would subserve many a useful purpose. As soon as every physicist is taught how to determine the angles and symmetry of a simple crystal, and every chemist is further enabled to define the crystalline forms of his artificial products, we shall have a large army of students for whom the transition to mineralogical work will be easy; then, and not till then, can we hope for any useful increase in the number of the members of this Society; then, and not till then, can we hope that our country will in its study of mineralogy take its proper place among the nations of the earth.

One more point I may mention. Until a few years ago there were two distinct Societies, a Mineralogical and Crystallological: they had objects far from identical, and in a more perfect world might have flourished side by side. The fusion of the two Societies without any extension of the title of the Mineralogical has had for its effect that we cannot satisfactorily demand what the Crystallological could—namely, the support of the organic chemist; and although it was understood at the time of the fusion that papers on the crystallization of artificial products,

organic or inorganic, should be within the scope of the joint Society, their inclusion in a *Mineralogical Magazine* would suggest a misnomer. The change or extension of our already lengthy title has its evident inconveniences, but it may be worthy of careful deliberation by the Society at some early date as to whether such an extension is not really necessary for the clearer definition of our objects if we are to enlist the sympathy of many who, though they may feel to be beyond the pale of a Mineralogical Society, yet by their investigation of the crystalline forms of the products of the laboratory may in the future, as in the past, throw light on the crystallography of the Mineral Kingdom.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following gentlemen have been appointed examiners:—

Mathematical Tripos, Part II.: Dr. Routh (Chairman), Messrs. W. Burnside, J. Larmor, and A. R. Forsyth.

Natural Sciences Tripos and 2nd M.B.: Dr. Hill (Master of Downing), Prof. Cleland (Human Anatomy), Prof. Stirling, Dr. Gaskell (Physiology).

Natural Sciences Tripos: Prof. W. G. Adams, Mr. W. N. Shaw (Physics), Prof. W. A. Tilden, Mr. H. J. H. Fenton (Chemistry), Prof. Lewis, Prof. Story-Maskelyne (Mineralogy), Mr. F. Darwin, Prof. H. Marshall Ward (Botany), Mr. W. F. R. Weldon, Mr. F. S. Harmer (Zoology).

Natural Science Tripos and Special B.A.: Mr. W. W. Watts, Mr. A. Harker (Geology).

M.B. and Special B.A.: Prof. W. G. Adams, Mr. S. L. Hart (Elementary Physics), Mr. H. F. Neville and Mr. H. J. H. Fenton (Elementary Chemistry), Mr. F. Darwin and Mr. S. F. Harmer (Elementary Biology).

2nd M.B. only: Mr. Pattison Muir and Mr. H. Robinson (Pharmaceutical Chemistry).

Messrs. W. Carruthers, F.R.S., and J. E. Marr are appointed examiners for the Sedgwick Prize to be adjudged in 1892.

The University Lectureships in Botany and Advanced Human Anatomy, tenable for five years, are vacant. Candidates must send their names to the Vice-Chancellor on or before November 30.

Open Scholarships and Exhibitions will be competed for at the following Colleges, beginning on the undermentioned dates: Mathematics, Pembroke, December 11; Trinity Hall, December 11; Queens', December 12; Mathematics and Natural Science, Gonville and Caius, December 7; King's, December 10; Jesus, Christ's, and Emmanuel combined, December 11; St. John's, December 11; Trinity, December 11; Sidney Sussex, January 1. The tutors will give full information.

The Sheepshanks' Astronomical Exhibition will be competed for on December 10 and 11 at Trinity College.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 15.—"Combustion in Dried Oxygen." By H. Brereton Baker, Dulwich College, late Scholar of Balliol College, Oxford. Communicated by Prof. H. B. Dixon, F.R.S.

In 1884, some preliminary experiments, published in the Journal of the Chemical Society, convinced me that moisture exerted an important influence on the combustion of carbon. Since that time experiments have been made, not only with that element but with several others, and the same influence seems to be exerted on the combustion of some, while no such influence could be detected in the case of other elements. It was discovered very early in the investigation that hydrogen, both free and combined, aided the union of carbon with dried oxygen, and therefore, for the new experiments on this and other elements, special attention was devoted to their purification from hydrogen. It was found that two of these elements, amorphous phosphorus and boron, had, like carbon, a very great power of occluding hydrogen. To eliminate it some of the elements were heated in a current of pure chlorine, while others were heated in sealed tubes with the chlorides of the elements, special precautions being taken to free the purified elements from all traces of the agents used in their purification. In this way the elements—carbon, sulphur, boron, and phosphorus, the latter in both red and yellow modifications—were found to have their combustion influenced by the dryness of the oxygen. Some chemical union was found to take place, the extent of which varied with the dryness of the substances. In no case, however, did it manifest itself by flame. Ordinary phosphorus was obtained so pure as not to glow in the oxygen dried by phosphorus pentoxide, though the pressure was increased and diminished in every possible way. If water was added, rapid combustion at once set in.

The elements—selenium, tellurium, arsenic, and antimony—were purified with as much care as was expended on the elements mentioned above. Their combustion was, however, not found to be affected in any way by the dryness of the gas.

In the course of the investigation two facts were discovered about the combustion (1) of amorphous phosphorus, and (2) of carbon in oxygen. Amorphous phosphorus is generally regarded as being incapable of true combustion. It is asserted that before amorphous phosphorus can be heated to its kindling point, it changes into ordinary phosphorus, which then burns. This has been proved not to be the case. Amorphous phosphorus was heated in a current of nitrogen, free from traces of oxygen, to 260°, 278°, and 300° in three experiments, without undergoing any change to the ordinary modification. If moist oxygen was substituted for the nitrogen, combustion took place at 260°. It seems, therefore, probable that amorphous phosphorus undergoes a true combustion in oxygen without previous change to the ordinary modification.

With regard to the combustion of carbon, it has always been a doubtful question which of the two oxides is first formed. Is carbon monoxide the first product, undergoing further oxidation to the dioxide, or is carbon dioxide the first and only substance formed? The problem seems incapable of direct solution. It is, however, open to indirect attack. When carbon is heated in a current of partially dried oxygen, a slow combustion goes on, and, though the oxygen is in excess, both oxides are produced. The amount of monoxide, however, is twenty times the amount of the dioxide. Experiments also show that this occurs at temperatures at which dry carbon dioxide is not reduced by carbon. The carbon monoxide must, therefore, be produced by the direct union of its elements, its further oxidation being prevented by the dryness of the gases. Confirmatory experiments were performed in which carbon monoxide was found to be produced by the slow combustion of carbon in air at 440°, a temperature too low for the reduction of the dioxide by carbon. It is probable that the ordinary combustion of carbon goes on in two stages, that carbon monoxide is first produced, and, if circumstances are favourable, this is further oxidized to carbon dioxide.

"On the Secretion of Saliva, chiefly on the Secretion of Salts in it." By J. N. Langley, M.A., F.R.S., Fellow of Trinity College, and H. M. Fletcher, B.A., Trinity College, Cambridge.

Heidenhain has shown that when saliva is obtained by stimulating the chorda tympani, the percentage of salts in the saliva depends upon the rate of secretion, so that the faster the secretion the higher the percentage of salts is up to a limit of about 0·6 per cent.

The authors do not find any rate of secretion beyond which an increase in rate fails to increase the percentage of salts in the saliva. The increment in the percentage of salts decreases, however, with each equal successive increment in the rate of secretion.

As a rule, in saliva obtained by injecting pilocarpine, the percentage of salts follows Heidenhain's law; the exceptions are probably due to the action of pilocarpine upon the circulation.

The percentage of salts in saliva obtained by stimulating the sympathetic is higher than corresponds to its rate of secretion, the saliva obtained by stimulating the chorda being taken as a basis of comparison; this sympathetic saliva may be secreted at $\frac{1}{100}$th of the rate of chorda saliva, and yet contain very nearly as high a percentage of salts.

Dyspnœa decreases the rate of secretion of saliva with a given stimulus, and if not too prolonged, increases the percentage of salts, and tends to increase the percentage of organic substance in the saliva.

Clamping the carotid during secretion has the same general effect as dyspnœa, but it causes a still more marked increase in the percentage of salts. Its after-effect is also much greater, and lasts longer.

Bleeding has a similar effect to dyspnœa and to clamping the carotid, but its most marked effect is an increase in the percentage of organic substance.

Injection of dilute salt solution, NaCl, 0·2 to 0·6 per cent., in sufficient quantity, considerably increases the rate of secretion of saliva; the percentage of salts in the saliva decreases, although the rate of secretion of salts usually increases; the percentage of organic substance decreases; that is, increasing the volume of the blood with dilute salt solution chiefly increases the rate of secretion of water.

Injection of strong salt solution increases the percentage of salts in saliva. This is in accordance with the recent observations of Novi, that the chlorine in the salts of saliva is increased for a given rate of secretion by increasing the percentage of sodium chloride in the blood.

Saliva produced by stimulating the chorda tympani, or by injecting pilocarpine, after a small dose of atropine has been given, contains a low percentage of organic substance and of salts.

The authors, like Werther, find that sub-lingual saliva has a considerably higher percentage of salts than sub-maxillary saliva.

If lithium citrate, potassium iodide, potassium ferrocyanide, and pilocarpine are injected into the blood, lithium can be detected in the first drops of saliva secreted, potassium iodide after the first six drops; potassium ferrocyanide cannot be detected at any stage of secretion.

The general result of these experiments is to show that the secretion of water, of salts, and of organic substance are differently affected by different conditions, and that the percentage composition of saliva is determined by the strength of the stimulus, by the character of the blood, and by the amount of blood supplied to the gland.

All, or nearly all, the arguments which have been adduced to prove that the secretion of organic substance is governed by special nerve-fibres, have their counterparts with regard to the secretion of salts, so that we might imagine at least three kinds of secretory fibres to be present. The experiments, on the whole, indicate that this complicated arrangement does not exist, but that the stimulation of a single kind of nerve-fibre produces varying effects according to the varying conditions of the gland cells.

Linnean Society, November 15.—Mr. W. Carruthers, F.R.S., President, in the chair.—On behalf of Mr. H. Bolus, Mr. J. G. Baker exhibited a specimen of *Eriospermum folioliferum*, a plant showing a very remarkable type of leaf-structure. It was figured by Andrews in his "Botanist's Repository" in 1807, and lost sight of until recently refound by Mr. Bolus in Namaqualand.—Prof. Stewart exhibited a substance which had been picked up on the sea-shore, the nature of which it had puzzled many to determine, its structure being regarded by some as animal, by others as vegetable. He proposed to submit it to careful microscopical examination.—Mr. J. E. Harting exhibited a South American bat from Trinidad (*Noctilio leporinus*), alleged to be of piscivorous habits, and remarked upon a similar habit which had been observed in a species of *Pteropus* in India.—A paper was read by Mr. B. D. Jackson, on behalf of Mr. H. Chichester Hart, on the mountain range of plants in Ireland, and was criticized by Mr. J. G. Baker, who gave an interesting sketch of the characteristics of the Irish flora.—Two papers were then read, by Mr. Sladen, on the mammals and birds collected by Mr. H. N. Ridley in Fernando Noronha, in the determination of which the author had been assisted by Mr. O. Thomas and Mr. R. B. Sharpe.

Physical Society, November 10.—Prof. Reinold, President, in the chair.—The following communications were read:—On the calculation of the coefficient of mutual induction of a helix and coaxal circle, by Prof. J. V. Jones. In arranging some experiments for determining resistance absolutely by Lorenz's method, the author had occasion to consider what form of standard coil was most suitable for accurate calculation, and chose a helix of large diameter with a single layer of wire. To obtain a sufficient number of turns requires considerable axial length, and Lord Rayleigh's approximate method of calculating the coefficient was found to be insufficient where an accuracy of 1/100 per cent. is required. A method of calculation is given considering the wire as a helix whose equations are $y' = A \cos \theta'$, $z' = A \sin \theta'$, and $x' = k\theta$, those of the circle being $y = a \cos \theta$ and $z = a \sin \theta$. Applying the formula obtained to a circle of 10 inches diameter placed concentric with a helix of 20 inches diameter and 4 inches long, the value obtained is $M = n \,.\, 53{\cdot}259$, whereas Lord Rayleigh's formula gives $n \,.\, 53{\cdot}317$. Dr. Fleming described a wooden anchor ring wound like a gramme armature, and having a secondary coil added, which he had devised as a standard of mutual induction, and used for determining capacity absolutely. In reply, the author said he had not considered the wire to have thickness, as he felt sure this would not affect the result for his coil by one part in 100,000. With respect to Dr. Fleming's anchor ring, he considered the difficulty of winding it sufficiently uniformly to be a great drawback to its general adoption.—On the upper limit of refraction in selenium and bromine, by Rev. T. Pelham Dale, read by Mr. Baily. In a former paper (read February 11, 1888) the author showed that an upper limit of refraction for selenium should theoretically exist about the middle of the visible spectrum, and the present communication describes some experiments which tend to confirm the prediction. On placing a thin film of selenium under a spectro-microscope, it was found to be opaque to rays above the green, and previous calculation had given 5295·7 as the limiting wave-length transmissible. Sulphur at ordinary temperatures should have its upper limit beyond the visible spectrum, but theory indicates that increased temperature will lower the limit. It is well known that sulphur darkens when heated, and when a film of boiling sulphur was examined under the spectro-microscope, all but the red end of the spectrum was absorbed. On cooling, the region of absorption gradually retreated towards the violet end. Selenium is also found to become more transparent as it is cooled, and its refractive equivalent is equal to that of sulphur multiplied by the ratio of its chemical equivalent to its density. Important optical as well as chemical relations thus exist between the two elements. The results obtained by bromine films were remarkably similar to those of selenium, the violet rays being entirely cut off. A method of solving the equation $a \sin \theta = \sin m\theta$ (on the limiting solution of which the upper limits of refraction depends), by a table of Eulerian integrals, is given in the paper, and an analogy between total reflection and the upper limit of refraction is traced.—Experiments on glass in polarized light, by Prof. S. P Thompson.—On a new form of standard resistance coil, by Dr J. A. Fleming.

Chemical Society, November 1.—Mr. W. Crookes, F.R.S., President, in the chair.—The following papers were read:—The constitution of the terpenes and of benzene, by Prof. W. A. Tilden, F.R.S. When oxidized under similar conditions with dilute nitric acid, the natural terpenes—australene, terebenthene, and hesperidene—yield less than 2 per cent., dipentene (terpilene) yields 27·6 per cent., and cymene and paraxylene yield 73 to 80 per cent. of paratoluic acid. Each of the four terpenes combines with two molecular proportions of bromine, and no more. Camphene, however, does not combine with bromine, and hence must be regarded as saturated in the usual sense. The author concludes that since the terpenes contain at most four units of available combining capacity, the nucleus of six carbon atoms which they all undoubtedly contain must be united into a closed chain containing at the most two double "bonds." Kekulé's benzene formula is a well-known representation of a ring of six carbon atoms, but must be abandoned, since the author considers that the terpenes are certainly not benzene derivatives. Kekulé's formula is open to the objection that it represents benzene as containing "ethylenic" carbon, for which there is no evidence at all. Moreover, a body of this formula, when treated with nitric acid, ought to yield abundance of oxalic acid. This the terpenes do, but the benzenoid hydrocarbons do not. Referring to this last statement, Dr. Japp, F.R.S., said that phenol on oxidation with alkaline permanganate gave a considerable quantity of oxalic acid; Mr. Groves, F.R.S., added that oxalic acid is obtained in quantity on oxidation of chloranilic acid; and Dr. Perkin, F.R.S., remarked that he had obtained a quantity of oxalic acid in preparing picric acid from phenol. Dr. Perkin also said that the low magnetic rotatory power of American turpentine was a probable indication of the non-existence of a nucleus of six carbon atoms. Mr. Wynne remarked that the production of α-naphthol by the distillation of phenylisocrotonic acid, a compound in which "ethylenic" carbon was undoubtedly present, might be quoted in support of Kekulé's benzene formula; and Prof. Armstrong, F.R.S., expressed the opinion that the evidence at disposal was entirely insufficient to enable us to determine the constitution of the terpenes with any degree of probability.—Some new compounds of magnesia with the halogens, a contribution to the

study of the electrolysis of magnesium chloride solution, by Messrs. Cross and Bevan. The authors find that the white substance separated at the cathode under the condition that the solution is not kept in circulation is a chloroxygen compound of magnesium, probably a magnesium hypochlorite. Similar compounds are formed on electrolyzing solutions of magnesium bromide and iodide.—The heat of dissolution of various substances in different liquids, by Mr. S. U. Pickering. The heats of dissolution of the nitrates and chlorides of calcium and lithium in water and in alcohol, and of bromine and iodine in various liquids, have been determined; and the results are held to support the author's view that the affinity of the radicles composing a salt molecule is not entirely saturated by their combination, and that the "residual affinity" of one of these radicles becomes entirely saturated by the solvent; the heat of combination of the atoms and the heat of dissolution of the molecule which they form being thus parts of the same chemical operation.—The criteria of plane and axial symmetry, by Prof. Armstrong, F.R.S. Wislicenus, in his now widely-known paper on the space arrangement of the atoms in carbon compounds, has termed compounds of the form $\begin{array}{c}\mathrm{a.C.b}\\ \Vert\\ \mathrm{b.C.a.}\end{array}$ *axially symmetric*, and those of the form $\begin{array}{c}\mathrm{a.C.b.}\\ \Vert\\ \mathrm{a.C.b.}\end{array}$ *plane symmetric*. In allocating these formulæ, he has argued, in a case such as is afforded by the two tolane dichlorides, for example, that the compound of higher melting-point (143°) is necessarily the plane symmetric modification, as it is produced on chlorinating tolane $\begin{array}{c}C_6H_5.C\\ \vdots\\ C_6H_5.C\end{array} + Cl_2 = \begin{array}{c}C_6H_5.CCl\\ \vdots\\ C_6H_5.CCl\end{array}$, and from the three possible configurations of tolane tetrachloride has arrived at the conclusion that on reduction it should yield the axially symmetric tolane dichloride in the larger quantity. Blank's experiments (*Annalen*, ccxlviii. 1) show that the two isomeric dichlorides are produced nearly in the proportion of two parts of that of lower melting-point (63°) to one of that of higher melting-point, and the axially symmetric structure is therefore, it would seem, as a matter of course, assigned by him to the dichloride melting at 63°. The author regards these views as being based on pure assumptions, and shows that all the facts at present known tend to prove that symmetric compounds—such as the para- or symmetric di-derivatives, or the symmetric tri- and tetra-derivatives of benzene, or the axially symmetric $\alpha\alpha$ or $\beta\beta$ modifications in the case of isomeric di-derivatives of naphthalene—have always the highest melting-point. The tolane dichloride of higher melting-point is therefore probably the axially symmetric modification. The majority of "alloisomerides" are compounds containing unsaturated carbon usually in association with one of the halogens or oxygen, and the author points out that it does not appear that this circumstance has yet been taken into account, or that the extent to which the peculiarities manifested by the negative elements are concerned in and may condition the isomerism has been in the least considered. The symbolic system introduced by Van 't Hoff, and adopted by Wislicenus, tends, moreover, to withdraw attention from the consideration of the possible effect of the peculiarities referred to, inasmuch as a "double bond" is represented as the precise equivalent of two, and a treble bond as that of three single bonds; which all observations show is a misrepresentation of the facts.—Derivatives of methylindole, by Dr. H. G. Colman.—Acetamide and phenanthraquinone, by Dr. A. T. Mason.—The action of ethylenediamine on succinic acid, by the same.

PARIS.

Academy of Sciences, November 19.—M. Janssen in the chair.—On the "Collection of the old Greek Alchemists," by M. Berthelot. The parts now presented to the Academy complete the publication of the Greek text and French translation of this great work. Part v. contains technical treatises of special interest on the goldsmith's art, the tempering and colouring of bronze and iron, bronze casting, iron-gilding, the preparation of gold-leaf, the colouring of artificial gems, the treatment of pearls, the preparation of lye from ashes, beer, soap, &c. Most of these treatises appear to have formed part of a great work on practical chemistry composed in the eighth and ninth centuries, and several are written in the Byzantine dialect. But some are of great antiquity, amongst others one dealing with the phosphorescence of precious stones.—On the satellite of Neptune, by M. F. Tisserand.—On the latitude of the Gambey mural circle at the Paris Observatory, by M. H. Faye. A method is proposed by which the exact latitude of the instrument itself may be directly determined, and the results controlled which have been obtained with other processes by M. Périgaud in the present year, and by others at earlier dates. M. Périgaud determines the latitude of the Observatory as 48° 51′ 10″·9.—Note on the stability of the French seaboard, by M. Bouquet de la Grye. The results of the comparative observations taken for some years past at the ports of Brest, Cherbourg, and Havre, tend mainly to confirm the general researches of Colonel Goulier. From the comparative tables it appears that the mean level diminishes in the direction from Brest to Havre; at Havre the annual subsidence seems to be about 2 mm., at Cherbourg 1 mm., at Brest nearly absolute stability.—A study of submarine navigation, by M. A. Ledieu. A survey is given of the futile efforts made in this direction previous to the invention of Whitehead's regulating pendulum in 1872; which, combined with M. Joseph Farcot's servo-motor, gave the true solution of the problem. From that time dates all real progress in submarine navigation.—On various methods of treating rabies, by M. Odo Bujwid. Since his visit to M. Pasteur's establishment in 1886, M. Bujwid has been treating persons bitten by dogs, either mad or suspected of being mad, in his laboratory at Warsaw. At first he followed the simple processes of inoculation of M. Pasteur, and of M. Frisch, of Vienna, with some failures in both cases. But during the last sixteen months he has adhered exclusively to the intensive or severe treatment, which has been applied to 370 patients without a single fatality.—Observations of Palisa's new planet (281), and of Barnard's comet (October 30, 1888), made at the Observatory of Algiers with the 0·50 m. telescope, by MM. Rambaud, Sy, and Renaux. The observations of the planet are for the period from November 3 to November 8; those of the comet from the 5th to the 8th of the same month.—On the subsidence of the land in France, by Colonel Goulier. In reply to General Alexis de Tillo's remarks on his previous note, the author points out that his conclusions on this subject are not put forward as final, but only as a probable hypothesis to be accepted until proved untenable.—On mountain-ranges and their relations to the laws of deformation of the terrestrial spheroid, by M. A. de Grossouvre. On purely theoretical considerations the author arrives at the conclusion that the zones of foldings are progressively receding southwards. This conclusion is entirely in accordance with the observed facts connected with the dislocation of the earth's crust, and the regularity of the phenomenon is regarded as a confirmation of the theory of the primitive fluidity of the globe.—On equalities of two degrees, by M. Michel Frolov. These researches have reference to the properties of groups of *n* numbers, whose first and second powers give respectively equal sums, properties which have not yet been studied by any other arithmetician.—Maximum spectrum of Mira Ceti, by Mr. J. Norman Lockyer.—On the mutual relations of meteorites and shooting-stars, by M. Stanislas Meunier.—Note on the tensions of various vapours, by M. Ch. Antoine.—On the decomposition of the haloid salts of silver under the influence of light, by M. F. Griveaux.—Hydrochlorates of benzidine: their dissociation by water, by M. P. Petit.

BERLIN.

Physical Society, November 2.—Prof. von Helmholtz, President, in the chair.—Dr. Brodhun gave an account of experiments which he had made, in conjunction with Dr. König, for the purpose of testing the fundamental law of psychophysics in connection with the sense of sight. These have already been described by Dr. König in a communication to the Physiological Society, previously reported in NATURE (vol. xxxviii. p. 464). In the discussion which ensued, the President spoke on the sensation of light derived from the resting retina (*Eigenlicht*). In connection with the preparation of the new edition of his "Physiological Optics," he had made experiments and calculations which showed that the *Eigenlicht* is much greater than has hitherto been supposed. Taking as a standard the unit used by König and Brodhun in their researches, the *Eigenlicht* has a magnitude of forty to sixty such units. It is characterized by the irregular brightness of the field of vision, giving rise to the sensation of a more or less coarsely punctated image with lighter and darker patches; it further leads to the result that with equally small intensities of illumination large objects are seen more easily than

small, so that the liminal intensity (*Schwellenwerth*) for small surfaces is considerably greater than for large.—Prof. Kundt exhibited a large number of photographs of spectra which had been prepared in his laboratory with a view to testing the action of light-absorbing substances on dry-plates. Spectra photographed on dry-plates which had been coloured with chlorophyll were especially interesting. They consisted of a bright strip ending near F, followed by a dark portion intercepted by an extremely bright line at the spot where the absorption-band of chlorophyll is present in the red. Plates stained with eosin similarly showed a bright strip corresponding to the absorption-band of this substance in the yellow, whose brightness was much greater than that of the rest of the spectrum. These experiments showed that the rays of light which are absorbed by the above colouring-matters exert an extremely active chemical action on the plates. Experiments made with a view to determining whether absorption of light has a similar effect on fluorescence yielded negative results. It still remains to investigate whether the maximum brightness of the spectrum photographed on a plate stained with chlorophyll corresponds exactly with the absorption-band of this substance, taking into account at the same time the influence of the solvent used for the solution of the chlorophyll on the position of its absorption-band. Prof. Kundt then exhibited a simple form of bolometer which, based on the principle described by Dr. R. von Helmholtz at a recent meeting of the Society, may be easily and cheaply constructed out of thin tinfoil, and is specially adapted for lecture experiments. The same speaker finally exhibited two selenium cells constructed by Uljanin, of Strasburg, in July 1887, and still extremely sensitive to the action of light.

Meteorological Society, November 6.—Dr. Vettin, President, in the chair.—Dr. Kremser gave an account of meteorological observations made during a balloon voyage on June 23 of this year. For the purpose of carrying out scientific observations on the lines of Welsh and Glaisher in England, and of Tissandier in France, von Siegsfeld had constructed a balloon fourteen metres in diameter.—Dr. Assmann described some ice-filaments which he had observed in a valley of the Harz Mountains during a three days' frost in October.

Physiological Society, November 9.—Prof. du Bois-Reymond, President, in the chair.—Dr. Virchow described, as based on his own original researches, the development of the cylindrical epithelium of the yolk-sac, thus amplifying the communication made at the previous meeting of the Society on the development of the blood, blood-vessels, and yolk-sac of the chick. He distinguished seven stages in the development of the epithelium, each of which he separately described and explained by means of drawings, diagrams, and preparations, which he exhibited.—Dr. Martius made a communication on new experiments which he had carried out with a view to refuting certain attacks which had been made on his investigation of cardiograms as laid before the Society in the previous year. It may be remembered that the speaker had connected the curves traced by the impulse of the apex of the heart on a rotating cylinder with the various phases of a cardiac cycle, by auscultating the heart, and recording each sound he heard by a mark on the same rotating drum. Since he had assured himself that he could record the above without any irregularity due to his own reaction-time, he considered that the point on the cardiogram which corresponded with the mark for the first sound of the heart was synchronous with the closure of the auriculo-ventricular valves: the point corresponding to the mark indicating the second sound of the heart he regarded as coincident with the closure of the semilunar valves. Objections were made to the above method, and the possibility of the observer's reaction-time not being zero was left out of account. In answer to these, Dr. Martius has now made some new experiments with a pendulum beating seconds which closed an electric circuit as it passed through the vertical: the current thus produced attracted an armature, made a clapper-like noise, and recorded the instant of its production on a rotating drum. A second circuit was arranged for momentary closure by the observer, yielding a recording mark on the same drum: this circuit was closed regularly each time the clapper was heard, and the two marks made in the way indicated above coincided to within differences of time of at most 0·03 of a second, an exactitude which amply sufficed for the investigation of the cardiograms. It may be remarked here, as a matter of theoretical interest, that the above is not a case really involving reaction-time, but only the recording of known signals which are repeated rhythmically at regularly recurring intervals. With these rhythmic stimulations the duration of the interval is usually *estimated*, and in such cases the variations in the time-value of the estimate are mostly greater than those just quoted. When, however, after some time the rhythm of the stimulations has been fully grasped by the observer, then the interval is no longer estimated, but the record is made with an exactly similar rhythm.

PRJEVALSKY'S FOURTH JOURNEY TO CENTRAL ASIA.

From Kiakhta to the Sources of the Yellow River, the Exploration of the Northern Borders of Tibet, and the Journey viâ *the Lob-nor and the Basin of the Tarim.* By N. M. Prjevalsky. (In Russian.) With 3 Maps, 29 Phototypes, and 3 Woodcuts. (St. Petersburg: Published by the Russian Geographical Society, 1888.)

IN this large quarto volume, which the indefatigable traveller brought out before leaving St. Petersburg for his proposed fifth journey to Central Asia, we have a general account of the journey he began at Kiakhta on November 20, 1883, and ended two years later at Lake Issyk-kul, in Russian Turkestan, after having visited the upper parts of both the Yellow and the Blue Rivers. As to the purely scientific description of the invaluable collections which were brought in by the Expedition, it has been undertaken by specialists and will be published separately.

Prjevalsky's aim during his fourth journey was to reach Lhassa, in Tibet; and it was in the hope that he might more easily make his way to that city that he started from Kiakhta, instead of taking the shorter route *viâ* Turkestan. His plan was to be at Lake Kuku-nor early in the spring; to buy provisions there, and to have them stored somewhere in South Tsaidam; and thence to proceed southwards, and to cross the north-eastern border-ridges of Tibet. The third part of the scheme could not be accomplished; and, after having visited the Upper Hoang-ho and the Upper Yang-tzse-Kiang (the Dy-tchu), Prjevalsky was compelled to return to his store-house, and thence he proceeded home *viâ* Lob-nor and East Turkestan. But the Expedition has thrown so much light upon the orography, the flora, the fauna, and the inhabitants of the outer terraces of Tibet, as well as of Eastern Turkestan, that one can hardly regret that the Russian traveller did not succeed in crossing the highlands to the north of the holy city of Buddhism.

The chapters devoted to the journey to the west of Kuku-nor will certainly be the first to attract the geographer, for only very brief accounts of that part of Prjevalsky's journey have hitherto been published. But the physical geographer and naturalist will also read with interest the pages devoted to the winter journey across the Gobi, to its terrible sand-storms, and the geological work of these storms, and still more the remarks upon the flora and fauna of the Nian-shan plateaus and the spring migrations of birds about Kuku-nor. It was in the Nian-shan that a new species of antelope, the *A. cuvieri*, was discovered. As seen from the drawing given by Prjevalsky, it differs widely from the next kindred species, the *A. gutturosa*.

It was only on May 13, 1884, that the Expedition reached the spot, Dzun-zasak, in South Tsaidam, where a store-house had to be erected. After having overcome considerable difficulties in getting camels and provisions, it started southwards in order to reach Lhassa. It crossed, first, the Burkhan-buda ridge, which rises like a wall from 7000 to 7500 feet high over the plateau of Tsaidam, and reaches the height of nearly 17,000 feet, without, however, attaining the limits of perennial snow. The Burkhan-buda is a border-ridge; it fringes the next and higher terrace of Northern Tibet, the lowest parts of which are from 3000 to 4000 feet higher than the Tsaidam plateau; and therefore it has but a gentle and short slope towards the south. At its southern foot, Prjevalsky found a broad valley, 13,400 feet above the sea, where flocks of wild *yaks* (*Poëphagus mutus*, a new species discovered by Prjevalsky) and *kuku-yamans* (*Pseudois nahoor*) live on the few grazing-grounds which can be found at such a height. A low range of hills separates this valley from the broad depression of Garmatyn, or Odon-tala, where the Expedition reached, on May 29, the upper part of the Hoang-ho and its two lakes, Jirin and Orin, so well known from Chinese sources, but never before visited by a European. "Now we saw the birth-place of the great river, we drank its water, and there were no bounds to our rejoicing," wrote the traveller in his note-book. He tried, of course, to explore the lakes, but a terrible snowstorm overtook the exploring party. Next day the ground was covered with two feet of snow, and the thermometer showed a frost of – 23° C., on June 1, under the 35th degree of latitude! The difficulty of moving on camels under such conditions may be easily imagined. But hunting was excellent, and Prjevalsky's companions killed numbers of the Tibetan bear (*Ursus lagomyiarius*). Alpine meadows, 16,000 feet above the sea, spread towards the south, but high mountain-ridges separate them from the Dy-tchu (the Upper Yang-tzse-Kiang), and it was only on June 22 that the party reached the Dy-tchu, in 33° 47′ N. lat., and 95° 54′ E. long. It flows in a narrow valley, at a height of 13,100 feet above the sea, and soon enters a narrow gorge between high mountains. The camels were in very bad condition, and there were no means of moving down the Dy-tchu, as it entered a narrow stony gorge. Neither was it possible to cross the rapid river, so that Prjevalsky was compelled to return. On the return journey the Expedition explored both the lakes of the Upper Hoang-ho, but it had to carry on regular fighting with several hundreds of Tangutes. It was thus obliged to abandon the exploration of the northern shores of the lakes, and to return to the store-house.

The attempt to reach Lhassa by this route thus proved a failure; and, in our opinion, a worse route could not have been chosen. True, while going due south from Dzun-zasak, Prjevalsky reached the lakes of the Upper Hoang-ho, and solved a great geographical problem; but then he had before him a mountainous region which he would have had to cross in an oblique direction—the series of ridges which accompany the great border-ridge of Eastern Tibet undoubtedly having a direction from the south-west to the north-east. Even if he had had horses, instead of camels, he would have met with insuperable difficulties. The fact is, that, having no knowledge of the orography of the highlands of Eastern Tibet, geographers draw on our maps the mountains of the Amdo as running *between* the problematic courses of the rivers which flow from Central Asia to Burmah and China; the ridges thus have on our maps a south-eastern direction, while in reality there is the greatest probability in favour of the mountain-ridges having a north-eastern direction, and being *pierced* by those rivers. The great border-

ridges of the great Central Asian plateau, which are known under the name of Great Khingan in the north, cannot terminate in the latitude of 35°. Probably they continue south-west as far as the Himalayas, and so it is most likely that the region of the Upper Yang-tzse-Kiang is filled with mountains running from the south-west to the north-east.

This view is supported by the results of Prjevalsky's exploration. In 1880, when he took from Dzun-zasak a south-western direction, and thus followed the foot of the highlands, he reached the Khara-usu with comparative ease. But when he went southwards and reached the Dy-tchu under the 96th degree of longitude, he could move neither east nor south. In the east he saw the gorges by which the Dy-tchu, which flows south-east, pierces the first of the series of the mountains that accompany the border-ridge. And further south he saw before him the continuation of the same ridge, and obviously could not cross it in an oblique direction.

All this becomes obvious when one attentively examines the map which accompanies Prjevalsky's last work. In fact, we see on that map that the two great lines of upheavals—south-west to north-east, and north-west to south-east—which so distinctly appear in Turkestan, the Caucasus, and Siberia (the chains running south-west to north-east being more ancient than those which run in the other direction) are as well pronounced in the southern parts of the great Central Asian plateau as they are in its northern and eastern parts. The whole of Central Asia appears, in fact, as a series of plateaus of various heights, which—very much like Bohemia in Europe—are bordered by chains having a direction from either south-west to north-east, or north-west to south-east.[1]

Although the Expedition failed to reach Lhassa, its observations on the climate, flora, and fauna of Northern Tibet are invaluable. The climate of the region; its poor vegetation, which has every year only a few days for developing its flowers and seeds, and nevertheless is strikingly rich in the numbers of its species; the mixture of Chinese, Himalayan, Tibetan, and Central Asian species which one finds in these highlands,—all this renders the borderlands of Tibet in Prjevalsky's description almost more interesting than the plateau itself.

We shall only refer to that part of the journey during which the Expedition moved north-westwards from the Dzun-zasak store-house to the small lake Gas, at the foot of the ridges Tsaidam, Garynga, Torai, Columbus, and Marco Polo's, which connect the Altyn-tagh with the yet unnamed highlands of the Upper Hoang-ho. Most interesting facts as to the nature of Tsaidam will be found in the chapter devoted to that part of the journey. Prjevalsky's winter excursion from Lake Gas enabled him to obtain an insight into the structure of the border-ridges which separate Northern Tibet from the lower terrace of Tsaidam (9000 feet above the sea). No less than three parallel ridges constitute that border-region. The outer ones are known under the names of Tsaidam, Garynga, and Torai; but these are not the highest of the series. The highest summits are gathered in the next row of mountains—the Columbus, Marco Polo's, and Prjevalsky's ridges (this last name has been given to it by the Russian Geographical Society). Behind them there seems to be a third series of ridges, and then begins the plateau (also intersected by several snow-clad ridges), which is not less than 3000 feet higher than the Tsaidam plateau, and thus reaches about 12,000 feet in its lowest depressions. Much remains, however, to be explored before we can have a clear idea as to the structure of the mountains which separate Northern Tibet from the Lob-nor depression. Mr. Carey has already cleared up some points, and we may hope that this part of Central Asia—relatively easy to explore—will be well mapped before very long. Let us mention also that on the high plateaus which Prjevalsky visited from Lake Gas he discovered a new species of *Ovis*, which he named *Ovis dalai-lamæ;* it slightly differs by its horns and coloration from all known species of the same genus.

Less than 150 miles separate Lake Gas from the Lob-nor, and so the Expedition went to that lake, which was reached early in February 1885. There the Expedition stayed fifty days; and two chapters of the work which we have before us are given to the description of the Lower Tarim and the Lob-nor (which rapidly dries up and becomes a mere marsh), its flora, fauna, and inhabitants. Many photographs illustrate these chapters, so that now we have an accurate idea of the nature and inhabitants of the great depression which ten years ago was quite unknown. From Lob-nor the Expedition went south-westwards to Khotan, and thus followed the foot of the Altyn-tagh, the Toguz-daban, and the "Russian" ridge, which border the Northern Tibetan terrace on the north-west. The Turkestan oases of Tchertchen, Keria, Niya, and Khotan were thus visited, and again we find much valuable information as to the nature and inhabitants of the country in the chapters dealing with that part of the journey, as also excellent photographs of the inhabitants. Especially interesting are the photographs of the moving sands with their "ripple-marks" made by the wind, of the gigantic holy willows around a spring in the oasis of Niya, and of mulberry-trees in Yasulgun. It would be impossible to give in a few lines an adequate impression of the information gathered by Prjevalsky during his journey on a relatively beaten tract in Eastern Turkestan. To take one instance, we have hitherto had a general idea of the oasis of Keria and the high border-ridge which separates it in the south from the high plateaus. Although Prjevalsky made only a short excursion in these highlands, he supplies us with a most vivid description of the ridge (nearly 20,000 feet high) and its outer spurs, its flora and fauna, its inhabitants—the mountaineer Matchins who dig their dwellings in the loess which fringes the highlands (a group of such dwellings is represented by a photograph)—and their manners and customs. One feature of the highlands of Keria is especially worthy of note—the great amount of rain which falls on them in June and July. During the twenty-five days (July 10 to August 5) which Prjevalsky spent on the outspurs of the Keria Mountains, at a height of from 12,000 to 13,000 feet, it rained and snowed nearly all the time; the clouds coming from Tibet being condensed as they reached the high Keria ridge. The water which falls on the loess soil is immediately evaporated

[1] See Mushketoff's "Turkestan"; also the articles "Siberia," "Turkestan," "Transcaspian," "Transcaucasia," and "Ural," in the "Encyclopædia Britannica," and "Asia" in "Chambers' Encyclopædia."

and re-condensed by the cold air of the snow-clad summits. The great amount of rain in the border-ridges is the more striking as in East Turkestan rain is exceedingly scarce, and there is but very little rain at a level below 6000 feet. Prjevalsky concludes that the heavy summer rains which fall in the Keria Mountains every year are due to the south-western winds coming from the Indian Ocean, and he maintains that the effects of the monsoon winds are felt even in the upper parts of the Hoang-ho.

From Khotan the Expedition went northwards, across the desert. It crossed the Tarim at the confluence of the Yarkand-daria and the Aksu-daria, at a height of 3100 feet above the sea. The river has there a width of 185 yards, and an average depth of from 3 to 4 feet at low water. The velocity of the current was 160 feet in a minute. From these facts, as well as from what he saw of the Lower Tarim, Prjevalsky concludes that the river can be navigated by small steamers from Lob-nor up to the confluence of the Yarkand and Aksu Rivers, and that the two latter can also be navigated to some extent.

The last chapter of the work is devoted to a general sketch of the political condition of Central Asia; but those who are acquainted with the recent literature of the subject will find little new in it. Geographers who may propose to explore Central Asia will find more to interest them in the introductory chapter devoted to the ways and means of travelling in Central Asia, with minute instructions as to how to organize expeditions. This chapter is full of practical hints. As to the scientific problems, Prjevalsky remarks that the present period of great discoveries in Central Asia is rapidly coming to an end. Few parts of what was formerly the great *terra incognita* remain to be explored; so that we approach a time when regular scientific expeditions will be necessary. There remain for investigation by means of "scientific reconnoitrings" the plateaus of Northern Tibet, the highlands of Eastern Tibet and Amdo, and Southern Tibet from Lhassa to Gartok. Three expeditions, lasting two or three years each, would suffice for the exploration of these three regions. The Pamir, with the Hindu-Kush and the Karakorum Mountains, the Eastern Tian-shan, the Altyn-tagh and the Nian-shan, the border-ridges of South-East Mongolia, the whole of the great Khingan, and North-Western Mongolia, close to the Siberian frontier, come next. Dealing with the subject of special scientific explorations, he recommends the Karashar and Si-nin for zoologists; the Tchertchen oasis for archæologists; Si-nin for ethnographers; Kashgar and Khotan, and Si-nin and Urga, for meteorologists; and the whole of Central Asia for geologists.

The present volume has three maps. One of them, on the scale of 67 miles to the inch, embodies the results of the four journeys of Prjevalsky, and is an excellent map of the eastern parts of Central Asia. Two maps, on the scale of 33 miles to the inch, embody the original surveys of the Expedition at the sources of the Yellow River and in East Turkestan. Numbers of excellent photo-lithographs, and three drawings representing new species of *Antelope* and *Ovis*, are inserted in the work.

Many years will elapse before the complete descriptions of Prjevalsky's rich collections will be published. All that can now be said is that they are in excellent hands. K. I. Maximowicz, A. A. Strauch, S. M. Hertzenstein E. A. Büchner, A. S. Woeikoff, and A. A. Inostrantseff are busily occupied with them, and the first parts of their common work are already in print. The first instalment of the first volume, containing the "Mammals," by E. Büchner, was issued at St. Petersburg a few days ago.

P. K.

FLOWERING PLANTS OF WILTS.

Flowering Plants of Wilts; with Sketches of the Physical Geography and Climate of the County. By the Rev. T. A. Preston, M.A. 500 pp. With a Map. (Published by the Wiltshire Archæological and Natural History Society, 1888.).

IN Wiltshire, the chalk downs which form so characteristic a feature of the geology and physical geography of the South of England reach their western limits. The area of the county is about 1300 square miles. It does not anywhere reach the coast, and forms a watershed from which small streams run in three directions, to the Severn, Thames, and English Channel. An elevated plateau of chalk on the south-east occupies more than half the area of the county. This is divided into two unequal halves by a natural depression, called the Vale of Pewsey, which runs almost due east and west, from Devizes to Hungerford. Along this hollow runs the Kennet and Avon Canal, of which the highest point, near Savernake, reaches an altitude of 500 feet. The northern portion of this chalk plateau is called Marlborough Downs, and the town of Marlborough stands nearly in the centre of it. The southern part is Salisbury Plain, the word plain as here applied conveying a delusive notion. Salisbury is at the south, and Stonehenge near the centre of this southern chalk tract. The highest points of these chalk downs reach a height of from 800 to 950 feet. The third section of the county, lying west and north of the chalk, is the fertile plain, underlain by greensand and oolite, along which the Great Western Railway runs between Swindon and Bath. The following extract from the introductory essay contributed to this flora by the Rev. J. Sowerby gives, in a few words, an excellent idea of the general characteristics of these different districts:—

"The great characteristic of the chalk plateau is its vast extent of grass-land, where sheep are extensively pastured. This space is more broken up each year for cultivation, but often exhibits great tracts of grass, with only occasional patches of furze. Only on the small patches of Tertiary scattered here and there, especially in the northern part, do we find wood (generally only underwood), excepting the grand forest of Savernake, twenty square miles in area, which can show timber of an age and size unrivalled in any part of England. The upper chalk hills were once, it is probable, covered with extensive copses, chiefly thorns. Remains of these still occur here and there; and individual trees of great size, some yet extant, others only traditional or historical, attest the former existence of a primæval wood. In the hollows of the downs, especially near the villages, there are spaces, often finely timbered, especially with elms. Monotonous as the surface of the downs may seem to be, the changes that present themselves are often singularly picturesque and varied. After passing, it may be for hours, over the gently sloping grass plains, all blue above, all green below, the traveller suddenly sees below him a

village embosomed in woods, with its picturesque church tower, surrounded by fertile and well-tilled land. Such an experience is obtained by the traveller who passes over the downs from Marlborough to Avebury or Wooton Basset, from Heytesbury to Chittern or Imber, from Warminster over Battlesbury, and the projecting spur of Bratton Castle to Steeple and Prood Ashton, on their picturesque hills.

"The part of the county lying north and west of the chalk plateau is of a different character. It is the plain country, as the other is the hill country of Wiltshire. They have been called 'the cheese' and 'the chalk.' This part includes, in the north, the country drained by the Thames and its affluent the Cole, and on the west that drained by the Bristol Avon. It consists of various geological strata, but chiefly of Oxford clay, a band of which, with an average breadth of nearly five miles, traverses this part of the county from north-east to south-west. Viewed from the outer edge of the chalk escarpment, this region presents the appearance of a vast, well-wooded, and fertile plain, bounded in the far distance by the hill-ranges of the adjoining counties of Gloucester and Somerset. The outer slope of the chalk plateau descends a hundred feet or so, its steep sides covered with turf or clothed with hanging wood, and then slopes gently down to the level. Here is a land of pasture-fields and hedges, overshadowed everywhere by elms, growing mostly in the stiff clay soil that overlies the Kimmeridge clay and Coral Rag. Beyond the level, in front, rises a line of hills of the Coral Rag formation. These hills again descend, with an abrupt slope, into the valley (or plain) through which the Avon flows. The most picturesque scenery is found on the outer slopes of the hills. The plain, though often finely wooded, is somewhat tame, though its gentle hills and dales are not wanting in a beauty of their own."

What is said in the introductory chapter about the climate of the county is not satisfactory. Mr. Sowerby sums it up as follows:—

"On the whole, Wiltshire has probably the most elevated surface of any English county. This gives it certain peculiarities of climate. Its average mean summer temperature is higher, its mean winter temperature lower, than those of any other English county."

In the Report issued by the Royal Horticultural Society, edited by the Rev. George Henslow, on the effect on garden plants of the severe winters of 1879-80 and 1880-81, full details are given for the county of the plants that were injured and uninjured. Taking what is there stated in connection with the full details about the native vegetation of the county which are given in the body of the present work, it is quite clear that the whole of the county belongs to the warmest of Watson's six climatic zones, the Inferagrarian, of which *Clematis Vitalba*, *Viburnum Lantana*, and *Ruscus aculeatus*, are three out of many characteristic plants. The Inferagrarian and Midagrarian zones are represented in England at sea-level; and two others, the Superagrarian and Inferarctic, in the hill-country of the North of England; the two coldest of the six, the Midarctic and Superarctic, being reached only amongst the higher mountains of the Scotch Highlands. So far as one can judge from the botanical point of view, Kent, Sussex, Surrey, Hampshire, and Wilts stand substantially on the same level as regards climate, and cover the whole extent of Watson's Inferagrarian zone, without reaching into the Midagrarian. Mr. Preston is an experienced climatologist and phenologist, and no doubt is quite aware that such is the case; but nowhere in the present work can we find a clear explanation of the true state of the case, which from the point of view of botanical geography is all-important.

Besides the introductory sketch of the physical geography of the county by Mr. Sowerby, and the chapter on its temperature and rainfall, there is one on its geology, with a table of the twenty strata represented in the county twelve of which belong to the Oolitic series, four to the Cretaceous, and four to the Tertiary. Mr. G. S. Boulger contributes a sketch of its drainage, on which Mr. Preston founds eleven districts, under which he classifies the localities of the rarer plants. Two of these drain into the Severn, two into the Thames, and the other seven into the English Channel. Out of the 500 pages, 430 are occupied with a catalogue of the flowering plants of the county, with such detailed localities for the rarities as have been noted. Great pains seems to have been taken to identify the species, and to trace out their dispersion through the different districts. The eighth edition of the "London Catalogue" is followed as a standard of nomenclature; and out of the 1760 species there registered for the whole of Britain, 849 have been found in Wiltshire. Of these about 50 are marked as introduced, and at least 50 more are reckoned as varieties in Watson's "Cybele," where the number of wild British plants, including ferns, is estimated at 1425. Of these 1425 species, 530 are spread over the whole of Britain, 600 scarcely reach into Scotland, 200 are characteristically boreal types, and 77 too local to be classified. Wiltshire yields two plants which are not known elsewhere in Britain —*Cnicus tuberosus* and *Carex tomentosa*—both widely spread on the Continent. Out of 600 austral types, 127 are characteristically eastern in England. These are mostly plants that prefer chalk and limestone, and are well represented in the county. Add 30 for ferns, and 780 species for Wiltshire will be about the number on Watson's scale of reckoning, and compares properly with the figures as given in tables on pp. 371-81, and elsewhere in the fourth volume of the "Cybele." This is a smaller number than the plants of Kent, Surrey, and Hants, and about on a par with Dorsetshire and Hertfordshire. In all these counties the boreal element of the British flora is substantially eliminated. The special deficiency or unusual rarity in Wilts is of the plants of sandy heatherland, such as the foxglove, *Ulex europæus*, the fruticose Rubi, and many of the Trifolia, and such grasses as *Aira præcox*, *Deschampsia flexuosa*, and *Nardus stricta*. Altogether the book is one which no one who is interested in the distribution of British plants can afford to neglect.

J. G. BAKER.

MR. DODGSON ON PARALLELS.

Curiosa Mathematica. Part I. A New Theory of Parallels. By Charles L. Dodgson, M.A. (London: Macmillan and Co., 1888.)

THIS small book came into the world a little too soon or a little too late for our comfort. It was offered to us for notice in mid-vacation, and thinking we should find something amusing, we incontinently accepted the offer. We found some amusement, for, contrary to the author's experience, we read the preface, which is rather drawn out, but here and there is brightened by a quaint

fancy or an odd quotation. We read also the appendixes, which are of a similar character with the preface; but then there remained the inner layer of the sandwich, which called for a most careful overhauling. Anyone who has read Mr. Dodgson's "Euclid and his Modern Rivals" (cited in our present notice as "E. and R."), is prepared to find close logical reasoning and acute remarks in any work he undertakes, and the reader of this booklet will not be disappointed in these particulars.

Euclid's Twelfth Axiom the author asserts to be *not* axiomatic, *i.e.* he has not met with any "bimanous biped" who accepts it as *intuitive* truth. His quest is to find a better axiom. At first sight—and the illustrative figure meets us on the cover and in other places—one is disposed to grant the truth of the Dodgsonian axiom, viz. that "in any circle, the inscribed regular hexagon is greater than any one of the segments that lie outside it." But the author is not restricted to a paltry *once;* he can equally well grapple with the problem, if his reader will grant that twice, four times, eight times, or, in mathematical parlance, 2^n times, the hexagon is greater than any one of the above-named segments. The principal part of the text consists of five definitions, six axioms, and seventeen propositions. Appendix I. contains alternative proofs of certain propositions consequent upon the general form of the author's axiom. The "distance" between two points figures as a definition ("the length of the shortest path between them") and as an axiom ("the length of the straight line joining them"). Prop. IV. is headed a "Theorem"; we should have thought it was a "Problem." It is:—"Given a triangle: to describe an equilateral triangle which shall "enclose it" (third line from end—for AE read DE). Prop. V. is an important one; it runs thus:—"Given a certain angle; and given that every isosceles triangle, whose vertical angle is not greater than the given angle, has its base not greater than either of its sides; to describe, on a given base, an isosceles triangle having each base-angle equal to the given angle" (line 5 from end, for "DE produced" read "BE produced"). In the corollary to this, the argument seems to us to be scamped: a hasty reader might think that Mr. Dodgson had *assumed* Euc. I. 32. We would close thus:—"Angle AFB is greater than angle ACB, ∴ greater than angle ABC, and *a fortiori* greater than angle ABF." Prop. VI. is all right, but how are the figures to be constructed if $n > 2$? The sum of the angles of a triangle is called, by Mr. Dodgson, its "amount." In Prop. VII. (interchange E and F in dexter figure) he shows that, "if α, β be two 'possible amounts'—that is, 'amounts' belonging to existing triangles—then every 'amount' intermediate to α and β is also 'possible.'" Prop. VIII. shows that there is a triangle whose angles are together not greater than two right angles (line 7 up, p. 17, for "=" read ">"; line 1 up, p. 18, for "ABD" read "ADB"). At this point comes the axiom, and Prop. IX. follows:—"An isosceles triangle, whose vertical angle is one-twelfth of a right angle, has its base less than either of its sides" (the corollary applies Prop. V. above). Prop. X. shows that "the angles of every equilateral triangle are together not less than one-fourth of a right angle." Prop. XI. establishes that "there is a triangle whose angles are together not less than two right angles." This is a long proposition. Props. VIII. and XI. are sound on the hypothesis which Mr. Dodgson seems tacitly to have adopted, viz. that the "amounts" of triangles are all in the same boat, either *all* greater than two right angles or *all* less than the same quantity. Surely it is, *a priori*, conceivable that the "amounts" may be variable, and then how will his proofs hold? Prop. XII. readily deduces, from the *previous reasoning*, that "there is a triangle whose angles are together equal to two right angles." Prop. XIII. proves that there is a quadrilateral figure with all its angles right angles (*i.e.* a rectangle); and Prop. XIV. shows that the opposite sides of such a figure are equal. But, "tell it not in Gath," Mr. Dodgson *takes up the rectangle*—we repeat it, takes up the rectangle—and *reverses* it, "so that A, B, may change places." We do not object, but how about the Irish bull (E. and R., p. 47)? But this is not the only surprise in store, for in Prop. XV., to prove that "there is a pair of lines, each of which is 'equidistant' from the other—that is, is such that all points on it are equally distant from the other line"—he makes a rectangle slide along on a straight line! Prop. XVI. proves that "the angles of every triangle are together equal to two right angles"; and Prop. XVII. winds up the story with showing "that a pair of lines, which are equally inclined to a certain transversal, are so to any transversal."

The appendixes repay perusal. Appendix II. discusses Euclid's axiom, and argues that, "though true in the sense in which *Euclid meant it*, it is *not* true in the sense in which *we take it.*" In fact, Mr. Dodgson contends that Euclid "excludes from his view both infinities and infinitesimals, and considers *finite magnitudes* only." This is rightly founded on Euclid's Book X. Prop. I. We cannot go into the matter further here, but commend this and Appendix III. ("How should Parallels be Defined?") and Appendix IV. ("How the Question stands To-day") to any reader who is interested in this crucial question. We can quite sympathize with the author, as in times past we have more than once done our little best in the same direction, when he recounts how, more than once, he, too, has "with clasped hands gazed after the retreating meteor, and murmured, 'Beautiful star, that art so near and yet so far.'" To conclude, Mr. Dodgson is "inclined to believe that, if ever Euc. I. 32 is proved without a new axiom, it will be by some new and ampler definition of *the right line*—some definition which shall connote that peculiar and mysterious property, which it must somehow possess, which causes Euc. I. 32 to be true. Try *that* track, my gentle reader; it is not much trodden as yet; and may success attend your search!"

OUR BOOK SHELF.

Primer of Micro-Petrology. By W. Mawer, F.G.S. (London: Office of *Life-Lore*, 1888)

THE task of introducing the student to any particular branch of science requires such selective judgment, such tact both in saying and in leaving things unsaid, that it is not surprising if many so-called "primers" fall short of the good intentions of their authors. Mr. Mawer, in this little book, presupposes "an acquaintance with the phenomena of pleochroism and the polarization of light," and hence refers only in the briefest manner to the methods employed in the examination of thin mineral

sections. He also, in his desire to be abreast of current literature, uses such terms as "allotriomorphic," "microfelsitic," "magma-basalt," without adequate definition or discussion; and in speaking of a "porphyritic groundmass" he will throw many beginners into confusion. If the student is to seek elsewhere for instruction both in the manipulation of the polariscope and in the use of technical terms, the book must be held to fail in its fundamental object as a primer. It will probably serve well, however, to remind the learner of the broader features that mark out one rock-forming mineral from another. The author, moreover, insists, as befits a geologist, on the purely supplementary character of microscopic study—a warning that seems more than ever needed when micro-petro-*graphy*, by the change of a few letters, has been exalted to the level of a science.

The statements in this book are essentially accurate, and the illustrations, excepting that of ophitic structure, may be useful in recalling diagrammatically what has been seen in actual sections. On p. 32, however, there is an incorrect account of the pleochroism of muscovite, which probably has arisen from a blending of two totally independent notes. On p. 36 the sections of augite should be described as having, not six, but eight sides; and talc reappears on p. 50 as a constituent of protogine granite. The cleavages in drawings on pp. 33 and 36 are not in every case consistent with the descriptions.

G. C.

Theoretical Mechanics. By J. E. Taylor, M.A. (London: Longmans, Green, and Co., 1888.)

So long as examinations on prescribed courses are in vogue, so long, we suppose, will text-books be written for them. The book before us has been prepared chiefly to help those who are studying for the elementary stage of the Science and Art Department's examination in the subject, but it also covers the requirements for London matriculation. There is not much scope for originality in a work of this description, and in looking through it we find ourselves in familiar, well-worn paths.

In his preface, Mr. Taylor states that he has endeavoured to make the subject comprehensible to the beginner, but we are afraid that his efforts to explain the difference between mass and weight will be far from successful. This is always a delicate point to touch upon, but we venture to say that few beginners will be likely to understand the explanation given on page 8. This is as follows:—"Whilst mass is always measured by weight, yet the two terms must be kept distinct, the weight being the amount of force which the attraction of the earth exerts on the mass. If g represent this attraction, W, weight of the body, m, mass, we have $W = mg$." Most beginners are likely to imagine from this that W should be equal to g, instead of to mg.

The book is well illustrated throughout with many new diagrams and several old ones from well-known text-books. Numerous examples, worked and unworked, are also given.

With the exception referred to, the book is on the whole well written, and completely covers the Syllabus. The admirable style in which it has been issued, and its comparative cheapness, will commend it to many teachers.

Instructions for Observing Clouds on Land and Sea. By the Hon. R. Abercromby. With Photographs and Engravings. 22 pp. (London: Stanford, 1888.)

The phrase *Nascitur non fit* may be applied to cloud observers with almost the same confidence as to poets; at least, such is the experience of most persons who have attempted to teach an ordinary observer to record cloud phenomena.

Mr. Abercromby's pamphlet, however, contains a valuable stock of instruction which may be placed in the hands of intending observers, and will at least indicate to them what they have to observe.

The actual nomenclature of cloud forms used by Mr. Abercromby is that which has been, for the time at least, rejected by the International Committee at the recent meeting at Zürich (Nature, vol. xxxviii. p. 491), but this is a minor matter. The illustrations of cloud perspective and cloud motion are new and good, while the difference between the motion of advance, the "propagation" of a cloud bank, and the rotation of the clouds within that bank is, for the first time, clearly stated. The importance of the R. point (radiation point), the point towards which the stripes of cirrus converge, is explained.

Mr. Abercromby concludes as follows:—

"It (cloud observing) cannot be learnt in a day, but with a little attention and practice the knowledge is soon acquired. The observer, who begins by taking simple cases of low, fast-moving clouds, till he has fully realized the meaning and importance of R. points, will soon attain such proficiency as will enable him to make valuable observations in the most recent branches of modern cloud science."

Laboratory Manual of General Chemistry. By R. P. Williams, A.M. (Boston: Ginn and Company, 1888.)

After a few preliminary matters, including some good rules for students in the laboratory, each two pages of this book has in large type consecutive directions for performing an experiment or exercise. The rest of the two pages is left blank for written notes. One hundred exercises are given, and they are of a quite elementary character. It is a pity that contractions are so frequently used, especially when there is a large amount of vacant space and so small an amount of matter. "Ap.: p.t., 4 rec., t.t., d.t., r.s." indicates to the student the apparatus he needs for the purpose of preparing hydrogen. It would have been better to adopt a recognized system of shorthand throughout, for that would have rendered the book more useful to some and quite useless to others, instead of troublesome to all.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Mr. Romanes on the Origin of Species.

What the *Times* said is substantially the same as what Mr. Romanes himself says on p. 366 of his paper: "The theory of natural selection is not, properly speaking, a theory of the origin of species: it is a theory of the development of adaptive structures. Only if species always differed from one another in respect of adaptive structures, would natural selection be a theory of the origin of species. But, as we have already seen, species do not always, or even generally, thus differ from one another." Very well then, I say, if this be true, it shrivels up the part played by natural selection to very small dimensions.

The second part of Mr. Romanes's reply consists of a complaint that when I quoted from his paper the words "natural selection not a theory of the origin of species," I did not see that they were "flatly falsified" by the section at the head of which they stood. I do not see it even now, because the section finishes with what Mr. Romanes oddly calls an "insinuation" "that Mr. Darwin's great work on the 'Origin of Species' has been misnamed." If this insinuation be just, then I further do not understand how Mr. Darwin's reputation for candour is to be saved except at the expense of his intelligence.

In the third part of his reply, Mr. Romanes says "he [Mr. Dyer] must surely be aware that other botanists who have more thoroughly considered the subject are dead against him in his general conclusion." I have perhaps as many opportunities as most men of knowing the opinions of botanists, and I cannot

say I am aware of anything of the kind. The "late Prof. Nägeli" may be dead against me possibly; but I was not aware that he was dead in any other sense. Nor do I see that as he insists (quite correctly as I think) on the inutility of family characters he can afford much comfort to Mr. Romanes, who regards them as generally adaptive.

I have devoted a good deal of time to the study of Mr. Romanes's paper published by the Linnean Society. I believe I have stated the conclusions to be drawn from that paper with tolerable accuracy. If I have not done so, I undoubtedly owe him a sincere apology. But I am bound to confess that, the more I study his views, the more I find myself in disagreement with him as to the inutility of specific characters; as to the utility and mode of origin of generic characters and those of higher grade; as to sterility as a primary specific difference; and as to the value of so-called physiological selection. In all these matters he is, I am satisfied, contradicted by botanical experience. I think if he had imitated the example of Mr. Darwin, and had carefully collected a large body of evidence on each of these points with a perfectly open mind, he would have found this out for himself. What, however, I view with less patience than his unsustained generalizations, is his persistent attempt to place them on the shoulders of the Darwinian theory. I have reluctantly arrived at the conviction that his only excuse for so doing is that he has fundamentally misunderstood that theory. At any rate, I cannot in any other way account for the strained interpretation which he has put on passages from Mr. Darwin's writings. I may give, as an example, the passage he quotes "to justify the insinuation" that the "Origin of Species" has been misnamed; the obvious drift of this does not relate to specific differences at all, but to those which are characteristic of families. It is easy to see, in fact, by a comparison of pp. 170 and 176 of the sixth edition, that the passage cited by Mr. Romanes was inserted by Mr. Darwin to meet the point raised by Nägeli to which I have referred above. Certainly I think that no one would have been more surprised than Mr. Darwin when he wrote the words could he have foreseen that they would be used to impugn the validity of the title of his theory and of his book. Everyone knows that Mr. Darwin was the fairest and most generous-minded of men. He constantly admits the possibility of explanations to which he really, however, did not attach much importance. Such admissions Mr. Romanes appears to me to treat as if wrung from a hostile witness. In my judgment this is entirely to misapprehend their significance or the spirit in which they were made. W. T. THISELTON-DYER.

Royal Gardens, Kew, December 1.

Natural Selection and Useless Structures.

IN his letter on "Mr. Romanes's Paradox" (NATURE, November 1, p. 7), Mr. Thiselton Dyer questions the existence of indifferent or slightly disadvantageous specific characters. That letter referred, in a highly laudatory yet somewhat deprecating manner, to a lately published (Proc. Roy. Soc., No. 269) obituary notice of Mr. Darwin; and it implied that Mr. G. J. Romanes, from his unfamiliarity with the study of species, did not quite know what he was talking about when he asserted that such indifferent characters do in fact exist. I, who claim to have had some slight experience in the practical discrimination of species, ask permission to make a few observations in your columns on the subject.

Everyone would, I suppose, regard the frequent absence of the toe-nail on the hallux of the orang as an indifferent matter, but I am inclined to consider the feeble development of that digit itself as a slightly disadvantageous one. However that may be, I am strongly of opinion that the abortion of the index in the Potto can never have saved the lives of the earliest individuals so distinguished. I have, as yet, heard no reason assigned for the life-saving action of the thumbless hands of *Colobus* and *Ateles*, or of the tail of the one chameleon in which alone (so far as I know) that organ is not prehensile. The metallic lustre of the peritoneum of some fishes is hard to explain by either "natural" or "sexual" selection; as also are such specific characters as the extension, or non-extension, of the premaxillæ to the frontals, or the pattern of the foldings of enamel and cement in various Rodents. The complexity of the teeth of *Labyrinthodon*, or the similar multiplicity co-existing in those of *Orycteropus* and *Myliobatis* (which can hardly have been derived from a common ancestor, though their resemblance extends even to microscopic structure), are unquestionably good taxidermic characters; yet they can hardly have been due to the action of natural selection, as I pointed out in my "Genesis of Species" in 1870. But if such "selection" cannot originate characters which form the diagnosis of a species, then it cannot possibly be the origin of such species. To say that the rudimentary index of the Potto is a character which, though itself useless, has been carried on the back, as it were, of some possible but unknown useful simultaneous variation which co-exists with it or did co-exist with it in some unknown ancestor is a purely gratuitous assertion. Such assertions are the less warranted because we have evidence that the energy of Nature's destructive forces has been exaggerated. Prof. Dyer tells us that natural selection is a hard taskmaster; but it is not, I think, so hard a one as some persons suppose. This seems to me clear from such facts as the finding of hares and rabbits in which an incisor tooth has grown so as to complete the circle it always tends to form—a condition which shows a remarkable preservation of life under extremely disadvantageous circumstances. A stoat, three of whose feet had been cut off at different times by traps, has nevertheless (I am informed) lived long enough for its injured limbs to heal so thoroughly that the beast could get a living on its one foot and three stumps. Cases of prolonged life under trying circumstances are not so rare. I recollect the skeleton of a monkey which must have long suffered from acute rheumatism in its native forests.

Prof. Dyer deprecates the admission, by the author of the obituary notice, that indifferent or slightly disadvantageous characters may be evolved in spite of "natural selection." But the obituary notice admits *much more than that*, since, according to its author, a maintainer of "natural selection" is free to affirm the genesis of species by sudden, considerable, definite variations, directly produced by the reaction of the innermost nature of an organism on the stimulus of its environment, according to precise innate laws of its being. This certainly is not "natural selection," as understood and taught by Mr. Darwin, and the inventor of a new term has alone the right to fix what its meaning shall be.

The statement of the obituary notice seems equivalent to an unintentional but virtual abandonment of "natural selection," while still retaining the name—reducing it, in effect, to that merely subordinate *rôle* we all admit that it plays. To call such a mode of origin "origin by natural selection" seems much the same thing as declaring an elaborately prepared theatrical transformation scene to be brought about by the chains and cords which prevent its moving pieces from passing beyond their assigned limits. The true meaning of "natural selection" is frankly declared by that distinguished biologist upon whose shoulders the mantle of the deceased prophet seems to have fallen. Prof. Lankester, in his article "Zoology" (in the last volume of the "Encyclopædia Britannica") has just given a most straightforward, lucid, and forcible representation of Darwinism. Nevertheless, the article (in the same volume) on "Variation" by Prof. Geddes, appears to me to be more in harmony with the facts of biology. It is, of course, open to anyone to say: "All species which succeed do so from some cause, and this may be metaphorically said to 'select' them." Therefore, since all causes are "natural" causes, every species which does succeed must succeed through "natural selection." This is equivalent to saying: "Nature is so conditioned as to produce the results it does produce"—an assertion most true, but somewhat trivial. When a term is so stretched as to mean "anything," it thereby comes to mean "nothing," and its use can serve no purpose save the preservation of a phrase it may be desired, for some reason, not to discard. ST. GEORGE MIVART.

Hurstcote, Chilworth, Surrey, November 28.

A Mussel living in the Branchiæ of a Crab.

LATE this autumn, while searching for Crustacea at Amroth, in South Wales, I found rather an exceptionally good specimen of the common shore crab (*Carcinus mœnas*), which I took back to the hotel to clean and preserve. On removing the carapace, I found a mussel living among the branchiæ, and fastened to them by means of its byssus. It was in good condition, and measured ⅜ of an inch in length. The carapace of the crab measured 2¼ inches wide by 1⅝ inches long. I could find no signs on the exterior of the crab of anything remarkable within, nor was there any damage to the shell, or hole through which the mussel could have passed. It seems that the mussel, while yet minute, or in a larval condition, must have been carried

into the branchiæ, along the ordinary passages, by the flow of water the crab urges through them; it must there have become entangled in the feathery branches, and lived in this unwonted habitat long enough to have grown to its present size, having its food carried to it by the same water that served to oxygenate the lungs of its host. W. R. PIDGEON.

42 Porchester Square, W.

The Pasteur Institute.

IN the article in NATURE under the above title the writer says (p. 74):—"The probability of rabies following the bite of a rabid dog is now definitely ascertained to be from 15 to 16 per cent. of those attacked." It would greatly assist all who desire to form an impartial estimate of the value of Pasteur's researches on rabies as far as they are deducible from a comparison of statistics, if the writer would state the facts and figures on which the above computation of 15 to 16 per cent. rests. The statement is repeatedly made, but the proof is never given along with it. It is obvious that, unless this percentage is proved beyond dispute, the statistical argument will be lacking in cogency and force, and leaves a loophole for attack by those who are ever ready to depreciate and oppose the brilliant investigations of M. Pasteur. ERNEST ALBERT PARKYER.

Blackburn, December 3.

The Zodiacal Light.

IN your issue of October 25 (vol. xxxviii. p. 618), Dr. Muirhead quotes a remark of Cassini's in contradistinction to the relation indicated in your issue of the previous week (October 18, p. 594). The remark has not escaped notice, but is, I think, directed to a variation of shorter period, abundantly exemplified in Weber's observations, and in no wise invalidating the relation in the note of October 18. As far as Cassini's numerical observations go, the relation of the 18th is fairly exemplified, as will be shown by the following figures:—

Year.	Number of Observations.	Mean Elongation, referring to March.
1683	4	51·3
1684	2	67·10
1685 (max.)	33	52·35
1686	26	56·28
1687	16	68·82
1688	2	51·53

There are also observations indicating that the appearance did not pass away in 1688. Missionaries report brilliant appearances in 1690.

Any statement beyond the existence of this shorter variation would be at present premature.

The number of observations do not permit of a sufficiently sharp determination of the critical epoch to assert the amount of lag. The best determination which I am at present able to make is as follows. The sun-spot maxima of 1848, 1860, 1871, and 1883, follow the minima of the zodiacal light by + 1, − 1·5, − 1·5, + 1·5 years respectfully. The sun-spot minima of 1856, 1867, and 1878, follow the maxima of the zodiacal light by + 1, − 1, + 2·5 years respectively.

As to the working hypothesis, the suggestions put forward by Huggins in the Bakerian Lecture for 1885 seem in slightly varied form to meet all the facts which I am at present able to bring to bear upon the subject. There is evidence in the variation in the light of Encke's comet, as well as in the disturbance of its motion, that approaching the time of sun-spot maximum it meets matter moving towards the sun which it does not meet at the time of sun-spot minimum. Whence this matter comes may perhaps be questioned.

Observations seem to have been very nearly dropped since Weber's death in 1883. I am sure Dr. Muirhead will join with me in calling the attention of observers to this subject, and in asking that those observatories favourably situated would give us continuous records both as regards place, spectrum, and polarization. O. T. SHERMAN.

Baltimore, Md., November 15.

The "Tamarao" of the Philippine Islands.

DANS le numéro d'"August 16" (vol. xxxviii. p. 363), vous donnez une lettre du Dr. P. L. Sclater au sujet du *Tamarao* de Mindoro. Je crois que le Musée de Dresde s'en est déjà occupé; mais, sans avoir eu connaissance de ce travail, j'ai publié une note dans le tome ii. de nos Mémoires (Trübner, London) concernant l'histoire naturelle de l'Empire Chinois (p. 90), sur le *Tamarao*. J'y constate que c'est un buffle, et je propose de le nommer *Bubalus mindorensis*. Il n'a rien de commun avec l'*Anoa* des Célébes, au moins en ce qui concerne les dents.

Je suis curieux de voir dans le prochain numéro des P.Z S. une opinion contraire à celle de 1878. En dix ans on fait du chemin.

Je vous serais reconnaissant, Monsieur le Directeur, d'insérer ce petit mot dans votre correspondance. P.-M. HEUDE, S.J.

Musée de Zikawei, près Shanghai, 15 Octobre.

THE EARLIEST RACIAL PORTRAITS.

THE earliest representations of races that are preserved to us have been strangely neglected hitherto. On the Egyptian monuments are carefully sculptured and coloured figures of the various races that fell from time to time within the reach of conquest, or that entered into relations with Egypt, dating from the third millenium B.C.; yet till last year no attempt had been made to secure copies of these, free from the inevitable errors of mere drawings. At the desire of the British Association I took up this work, and made a series of casts of 280 heads from the sculptures, besides noting the colours of all paintings of races that I could find. These casts I then photographed, and the prints of the photographs can be obtained at cost price of printing.[1] These photographs are the source of the blocks (prepared by Messrs. Harper and Brothers) used in this paper, which, therefore, are perfectly automatic copies of the original sculptures.

In a recent article (NATURE, August 2, p. 321) Prof. Sayce has already noticed some of the conclusions to be drawn regarding a fair race in Palestine, so that it is needless here to repeat his statements; the actual portraits will, however, enforce his conclusions. The Amorites, who occupied the whole of Palestine, are seen (Fig. 1) to have fine though powerful features, quite different from the Jewish-Assyrian or the Egyptian types, with dolichocephalic heads; a type of face quite in accord with the light complexion and red-brown hair which they appear with in a painting of about 1500 B.C. They differ thoroughly from the features of the surrounding races of Hittites, Philistines, and Bedawin, as sculptured by the same artists, so that we are clear of the influence of mere conventionality. The Thahennu of Northern Africa, the Kabyles of modern times, show (Fig. 2) closely the same features, with only a slightly different beard and the long lock of side hair characteristic of the peoples of that region. Of the very few other portraits of Aryans that appear in Egypt, one of the most interesting (Fig. 3) is the primitive Greek woman, one of the captive Hanebu, or "lords of the north" (1400 B.C.). This has a very expressive and intelligent face, and the wavy sidelock and back hair recall the archaic Greek sculptures and vase-paintings. The stone has been unfortunately injured, but this precious proto-Greek is the only one remaining of the group.

In considering the origin of the Egyptians themselves, we are met with the difficulty that they are unlike any of the well-known neighbouring races. On the monuments we find, however, the Punites, or people of the southern shores of the Red Sea; and the resemblance between their features and those of the Egyptians is strikingly close. This noble of Pun (Fig. 4), has so precisely the face of Seti II, that either might be intended for the other. The evidence of relationship is not only in feature; the Egyptians coloured themselves as the red race, in contrast to the yellow Libyan, the brown Asiatic, and the black Negro in the four great divisions of mankind: they also colour the

Punites of the same red. In their civil relations likewise they show some signs of a community of origin: the Egyptians never made war on the Punites, while peaceful intercourse is repeatedly found, under Sankhkara (2800 B.C.), Hatasu (1600 B.C.), Ramessu III. (1200 B.C.), and others. The land of Pun was called "the divine land" by the Egyptians, and the typical form of the beard of the Egyptian gods is that of the noble of Pun above. Unfortunately we know so very little of the archæology of Somali Land and Yemen, which appear to be the ancient Pun, that it is hopeless at present to obtain clues from there; but the recent report of Colonel Haig on the extraordinary terracing of the hills on the Arabian side with stone walls to a height of 6000 feet, the great buildings mentioned by Hamdāni (tenth century A.D.), and the massive ruins, with blocks 13 feet long, at 70 miles in the interior from Aden,[1] all show that this region has been at some time a seat of civilization. It is not too much to hope that British or Italian energies there may yield some authentic and accurate accounts of the antiquities around Aden and Asab.

The source of the Hyksos, or "shepherd kings," who

FIG. 6.—North Syrians.

invaded Egypt about 2300 B.C., has been much discussed, and one special object of my work was to get a good profile of the Hyksos sphinx in the Bulak Museum (Fig. 5).

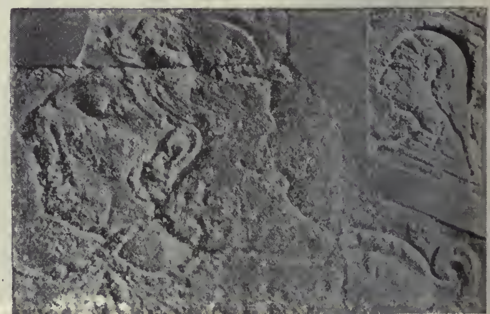
The features are quite peculiar, and unlike those of any Egyptian or other race usually represented. But on the north wall recently uncovered at the temple of Luxor, precisely the same face is found (Fig. 6), both in profile and full face, among people of Northern Syria.

The frontal projection, the horizontal eye, the precise curves of the nose, the peculiar form of slope beneath it, the lips, and the angle of the beard, are identical throughout; while the very thick bushy hair in the Syrian parallels the massive locks with which the Hyksos always represented themselves. Further evidence on the Hyksos has just come to light. On a statue found by M. Naville at Bubastis are the names and titles of a Hyksos king (*Academy*, September 1, 1888, &c.), Khian, which at once links to the Greek form Ianias of Manetho's dynastic lists, and appears to be identical with the name Khaian which occurs twice among the chiefs of North Syria, about 1000 B.C., in the Assyrian annals. Thus there is a confirmation of the view that the Hyksos were a people from Northern Syria, and further research should follow on these lines.

[1] Described to me by Colonel Johnson Pasha.

Of the Khita, or Hittites, there are several portraits, of which the most characteristic (Fig. 7) is that of the king (1200 B.C.). All of these are closely alike, and could not be mistaken for any other race on the monuments. The very low and retreating forehead, the large curved nose, and beardless receding chin are the essential points; and it is just these peculiarities which are most marked in the sculptures of the Hittites executed by themselves in their own cities. The general view now is that they must have been a Mongolian race, who held a military occupation of the lands around their own country, much like the Turkish rule of modern times. Their colour on the paintings is a moderate brown or browny yellow; the eye brown, and the hair black or brown. They are thus completely different from the fair Amorites, the red-brown Bedawin, or the yellow Phœnicians which surrounded them.

The value of the series of photographs lies not only in the study of one or two special races, but in the general information on the characteristics of the people of all the countries around Egypt at about 1400 B.C. What is much needed now is an equally complete and comparable series of portraits, in profile and full face, of the modern races which are supposed to be the representatives of these.



From Harper's Magazine. Copyright, 1888, by Harper & Brothers.

FIG. 7.—Hittites.

Until we have the recent portraits for comparison, the full value of the information which the Egyptians have so carefully recorded cannot be made available. It is to be hoped that some amateur will take scientific photographs in Syria, North Africa, and other countries before long.

An interesting study of the mixture of races may be made from the coloured wax paintings of the Roman age which I discovered this year in the Fayum. From those we see how largely Greek and Italian blood penetrated into Egypt far inland, and how it became mixed with the native race; showing that the Copt, though pure from Arab admixture since the Muhammedan conquest, is far from being of a pure race. We have therefore in the Copts a most interesting example for study; as the effect of climate in unifying a heterogeneous mixture, and subduing elements foreign to the country, can be here observed without any admixture of fresh races for twelve hundred years. A thorough anatomical study of the average Copt in comparison with the elements of ancient Egyptian, Negro, Ethiopian, Arab, Greek, and Roman, would throw light on the great question of climate *versus* race in the causation of characteristics. We have a specimen race duly compounded, and then safely set apart for future examination, owing to the power of fanaticism, which has been an absolute barrier to further combinations.

W. M. FLINDERS PETRIE.

BRITISH TERTIARY VOLCANOES.[1]

DURING the last twenty-seven years, the study of the volcanic rocks of the British Isles has been a constant and favourite pursuit with Dr. A. Geikie. It is now seventeen years since he read before the Geological Society of London the most important of the numerous memoirs which he had from time to time up to that date put forth on this subject. It was the well-known paper on the Island of Eigg, and was intended to be the first of a series of papers descriptive of localities where the characteristic features of the British volcanic rocks are well displayed. But man proposes: for the promised continuation of the series geologists have waited long and anxiously, no further instalments having till now appeared. The delay however, though trying while it lasted, has been productive of good result in the end; for we have now the long-wished-for consummation, not scattered through a long string of isolated papers, but in one connected whole. Dr. Geikie has garnered his harvest, and has summed up the results of the labours of more than a quarter of a century in a memoir which may fairly be looked upon as one of the most important of the contributions to the geological history of Britain which have seen the light since the days of William Smith.

And it gives to this elaborate communication a further importance that it is controversial as well as descriptive. In January 1874, Prof. J. W. Judd read before the Geological Society a paper "On the Ancient Volcanoes of the Highlands." It is a singularly fascinating production; its story is concisely and graphically told, and hangs well together; and I shall not easily forget the interest with which I read it for the first time, and which frequent reference to it subsequently has not abated. But Dr. Geikie's study of the subject has led him to conclusions directly in the teeth of two at least of the most important of those arrived at by Prof. Judd. Both authorities are agreed that the great basaltic plateaus of the Western Islands of Scotland and the North-East of Ireland are formed of sheets of sub-aërial lava piled one above another, the products of a long series of eruptions. Prof. Judd holds that the lavas were poured out from great central volcanoes of the type of Etna and Vesuvius, and he has endeavoured to fix the sites, and form an approximate estimate of the size of these volcanoes. Dr. Geikie is unable to find evidence for the former existence of central volcanic piles, and he believes that the lavas were emitted from fissures and numerous scattered vents of inconsiderable size. Again Prof. Judd thought he had established a threefold order of events during the period of volcanic activity. The first series of eruptions was marked by the discharge of lavas belonging to the acid class. Then came an abatement or cessation of the volcanic energy, and during a quiescent interval the cones and products of this period were largely denuded. Volcanic activity was resumed during the second period, but its products were of the basic class, and now form the basaltic plateaus. During the third period the volcanic energy was dwindling down, and had so far spent itself that it was equal to the production only of sporadic cones of small size, which are paralleled with the "Puys" of Auvergne.

And Prof. Judd further maintained that the great intrusive masses of granite and gabbro, which now form some of the boldest heights of the district, are the hardened contents of the reservoirs which fed the volcanoes of the first two periods. They had originally been buried beneath the cones that were heaped over them by the eruptions, and have been bared by denudation. The granites belong to the volcanoes of the first period, and Prof. Judd maintained that a gradual passage could be traced from them into sub-aërial lavas of acid composition that were emitted during that period. Similarly the gabbros were relegated to the second period, and pass gradually into its basic lavas. Dr. Geikie on the other hand brings an overwhelming mass of evidence to show that the intrusive masses of granite and other acid rocks are younger than the plateau-basalts. He mentions nothing that can possibly correspond with the sub-aërial sheets of acid lava which Prof. Judd states were poured out during his first period; he shows, indeed, that the one solitary known instance of a true superficial stream of acid lava is that of the Scuir of Eigg, which is unquestionably considerably younger than the plateau-basalts.

Though Dr. Geikie does not express a positive opinion on the subject, it seems to me that there is nothing to forbid our looking upon some at least of the smaller vents which he describes as Puys as belonging to Prof. Judd's third period. The vent, for instance, at Faskadale (p. 106) must be later than the great acid protrusions.

It is a serious matter for one whose acquaintance with the field of dispute is but slight to endeavour to hold the balance fairly and evenly between the conflicting views of two such eminent authorities, who have both made a study of the ground itself. Nor is the delicacy of the task diminished by the fact that the disputants have been for many years among the writer's most valued brethren of the hammer, and that to their teaching and example he owes more than can be put into words. This circumstance has fortunately however a certain advantage, for in attempting to decide between the conclusions of two equally valued and equally respected friends he will at least be free from any suspicion of partiality.

Some general considerations may be noticed before coming to detailed criticism. Dr. Geikie has known the ground ever since he was a boy: he has roamed over it again and again; he has had opportunities without number of reviewing, and in some cases of correcting, his first impressions. He has had, to some extent, the assistance and co-operation of his colleagues on the Geological Survey, and has had free access to all the details of their elaborate surveys. I believe I am right in saying that Prof. Judd was able to devote to his examination of the district the summer months of not more than two or three years. Without in the least implying that his observations were hasty, it must be clear that his opportunities for going into detail were very inferior to those of Dr. Geikie.

Further I am bound to confess that, though I was fairly carried away by the charm of Prof. Judd's paper, he did not succeed in bringing conviction to my mind to the same extent as the perusal of Dr. Geikie's memoir has done. His story had on the face of it an air of reality, but his statements were broad and general, and I could not help wishing that he had interpolated among his sweeping conclusions some details of the evidence on which those conclusions were based. I should have been sorry to miss the bold and strikingly graphic sections of his folding-plate; but I should have liked to have had, in the text, woodcuts, such as those which crowd Dr. Geikie's memoir throughout, of the actual exposures out of which those generalized representations had been constructed. It is easy to imagine good reasons for the omission of these details in Prof. Judd's paper, but all those who have made it a business of their life to cultivate a healthy tone of scepticism must have regretted their absence. No such charge can be brought against Dr. Geikie; more than sixty woodcuts, most of them representing actual sections, give ample opportunity for deciding for or against the sufficiency of his evidence.

We may now examine more in detail the main points of difference between the two readings; and, first of all, as to the vents from which the lava-flows were discharged.

[1] "The History of Volcanic Action during the Tertiary Period in the British Isles." By Archibald Geikie. LL.D., F.R.S., Director-General of the Geological Survey of the United Kingdom. Transactions of the Royal Society of Edinburgh, vol. xxxv., Part 2. (Edinburgh: R. Grant and Son, 1888.)

Dr. Geikie relies on the absence of any obvious vent from which the molten matter flowed. But surely the huge orifice of Strath, in Skye, was large enough to have served such a purpose. True there are appearances which seem to show that some of the plateau-basalts once extended right across the mouth of this funnel, but Dr. Geikie himself admits with perfect candour that the relation of this neck to the plateau-basalts does not admit of satisfactory treatment, owing to the destruction of the evidence by later intrusion of masses of granophyre in its immediate neighbourhood, and likewise to enormous denudation. I see nothing unlikely in the supposition that, from this enormous funnel, basaltic lava may have flowed in a manner to be shortly described; that the chimney became afterwards choked by agglomerate, too coarse to be spread far over the neighbourhood; and that, above all, basalt emitted from some new adjoining vent may have afterwards extended itself. Dr. Geikie further lays stress on the uniformity of the plateau-basalts in petrographical character, thickness, and persistent flatness, and on the almost total absence of interbedded fragmental deposits; and he maintains that these distinctive characters lead us to seek the modern analogues of the volcanic phenomena, not in large central cones like Vesuvius and Etna, but in the vast basalt-fields of Western America, where the lavas have issued from innumerable minor, and sometimes almost imperceptible, vents. With the first part of this opinion everyone must, I think, side with Dr. Geikie; but the method of formation which he advocates is by no means the only one possible or likely. Ever since I read Captain Dutton's account of the Hawaiian volcanoes,[1] it has seemed to me that it is to them we must look, if we are to understand the machinery by which great lava-plateaus have been produced. Speaking of the enormous flow which issued from Mauna Loa in 1855, he says: "As I looked over this vast expanse of lava, I was forcibly reminded of the great volcanic fields of the western portion of the United States, where the eruptions are of such colossal proportions that they have received the name of massive eruptions." After noticing Richthofen's view that these lavas had been poured forth through great fissures, and stating that the volcanic rocks of Western America, well as they are laid open to view, would be considered relatively obscure by one who has had an opportunity of inspecting the recent lavas of Mauna Loa, he goes on thus:—"I am by no means certain that Richthofen's conclusions are wrong. But here is a lava-flow, the dimensions of which fully rival some of the grand Pliocene outbreaks of the West, which demonstrably differs in no material respect, excepting in grandeur, from the much smaller eruptions of normal volcanoes" (*loc. cit.*, p. 156). But the differences between the modes of action of volcanoes of the Vesuvian and the Hawaiian types, whether we designate them as material or not, are striking enough, and they are just those which seem to have accompanied the discharge of the plateau-basalts we are now engaged with. Captain Dutton has well described them. "Mauna Loa and Kilauea," he says, "are in many important respects abnormal volcanoes. Most notable is the singularly quiet character of their eruptions. Rarely are these portentous events attended by any of that extremely explosive action which is characteristic of nearly all other volcanoes. The lava wells forth like water from a hot, bubbling spring; but so mild are the explosive forces that the observer may stand to the windward of the grandest eruption, and so near the source that the heat will make the face tingle, yet without danger. A direct consequence of this comparatively mild and gentle behaviour is the absence of those fragmental products which form so large a portion of the products of other volcanoes" (*loc. cit.*, pp. 84, 85). Fissure-eruptions are, to say the least, hypothetical; but here we have a way in which huge lava-fields, of the type of basaltic plateaus, are being produced before our eyes. The universally adopted canons of geological reasoning leave us no alternative as to which of the two explanations we should favour.

[1] United States Geological Survey, Fourth Annual Report, 1882–83.

But if the view just expressed be correct, we ought certainly to find some indications left, even among these ruined volcanoes, of the position of the vents from which the lavas issued. And here I cannot help going a long way with Prof. Judd in thinking that the great eruptive bosses of gabbro in Skye, Rum, Ardnamurchan, and Mull, are plugs filling in some of the main orifices of discharge. Prof. Geikie lays stress on the facts that the gabbros send off intrusive sheets into the plateau-basalts, and even overlie them. But this proves merely that the plugs which now fill the vents are later than the plateau-basalts: the vents themselves may be older. There must be some reason why the great intrusive bosses cluster thickly round a few centres, and are elsewhere conspicuous by their absence, and the following seems not unlikely. It was at these spots that vents were opened early in the volcanic period; from them there flowed, in the mild undemonstrative fashion of the Hawaiian volcanoes, the lavas which now build up the basaltic plateaus; as sheet was laid down upon sheet, the chimney gradually rose in height; and when, for this reason, and perhaps also on account of a temporary abatement of volcanic energy, the lava was no longer able to flow out at the top, it solidified in the vent, and, being under pressure, hardened into gabbro instead of dolerite. And indeed, though Dr. Geikie speaks of the eruption of the gabbro bosses as an event sufficiently marked and independent to characterize a distinct epoch in the volcanic period, he at the same time expresses himself in a way that shows he shares in the view I have just put forward, for he says: "We must remember, however, that the gabbro in many places found its readiest ascent in vents belonging to the plateau-period."

So far then the views of Dr. Geikie and Prof. Judd may admit of modifications which render them less conflicting than they seem at first sight. But there is one point on which reconciliation is impossible, viz. the nature and relative date of the eruptions of acid composition. Prof. Judd recognizes not only acid eruptions of the massive type—granites and their allies—but he speaks of thick bodies of felstones, disposed in regular sheets and of amygdaloidal structure, which alternate with beds of scoriæ, lapilli, and ashes, that lie upon the skirts of the central bosses of granite. These he believes to be the remnants of a volcano formed mainly of acid lavas, which was piled up and largely ruined by denudation before the discharge of the plateau-basalts began. The existence of the granite bosses admits of no doubt; but Dr. Geikie has depicted numerous sections which leave no doubt that these rocks intrude into the basalts and gabbros, and are therefore of later date than them. Now that all these details are before us, the question of relative age can admit of only one answer, but it is evidently a point on which observers, who had not opportunities of entering minutely into details, were apt to go wrong. Both Principal J. D. Forbes and Prof. Zirkel seem to have come to the same conclusion as Prof. Judd, and Dr. Geikie has supplied the explanation. "That there should ever have been any doubt," he says, "about the relations of the two eruptive masses is possibly explicable by the facility with which their junction can be observed. Their contrasts of form and colour make their boundary over crag and ridge so clear that geologists do not seem to have taken the trouble to follow it out in detail. And as the pale rock (granophyre or granite) underlies the dark (gabbro), they have assumed this infraposition to mark its earlier appearance." All this is graphically brought out in Fig. 43 of Dr. Geikie's memoir, which is reproduced here (Fig. 1). Anyone trusting to surface-feature

FIG. 1.—View of the hills on the south side of the head of Loch na Keal, showing the junction of the granophyre and the bedded basalts. One bird, the bedded basalts of the Gribon plateau; two birds, the bedded dolerites and basalts of Beinn a' Chraig adhering to the northern slope and capping the hill; three birds, summit of Ben More, with A'Chioch to the left and the top of Beinn Fhada appearing in the middle distance between them; four birds, the granophyre slopes of Beinn a' Chraig with the great dyke-like mass of felsite on the left.

FIG. 2.—Basic veins traversing Secondary Limestone and Sandstone on the coast cliffs, Ardnamurchan.

FIG. 3.—Outline of the hills of the Island of Rum, sketched from near the Isle of Eigg.

might well fancy that the basalts marked by two birds lay upon, and were newer than, the granophyre marked with four. Let us all take warning thereby.

But it is time to leave this perilous ground, and come to matters on which there can scarcely be difference of opinion. If it were desired to direct a student to a paper from which he could gather a clear and comprehensive view of the manifold forms under which volcanic products present themselves, not treated in the abstract but brought home to him by concrete examples, none could be found better fitted for the purpose than the memoir before us. And if a beginner would learn a lesson of the way in which a geologist goes to work when he wishes to unravel and interpret a complex group of geological documents, he will here find both precept and example. A point or two may be specially noticed. The enormous area which is seamed across by dykes, presumably of the same date, enables us to realize the importance of underground volcanic action, which is necessarily hidden from view in the case of volcanoes now in activity. I first learned this lesson while traversing a similar district, fully three times as large as that treated of by Dr. Geikie, in South Africa In connection with the striking parallelism of a large number of the dykes, reference is fittingly made to the classical paper of Mr. Hopkins, which he used so pathetically to complain had proved of interest neither to geologists nor mathematicians. But the mention of this paper again makes me lapse into criticism. When I first, many years ago, made acquaintance with Mr. Hopkins's investigations, two of his conclusions struck me as on the face of them so improbable physically, that, though I felt the presumption of the notion, I could not help suspecting some hitch in his analysis. One such oversight, so obvious that I can now hardly believe it to have been made by so first-rate a mathematician, I then detected. The other I have no doubt will reveal itself to careful inquiry. But from a hasty reperusal of the paper I do not think that either of these slips, supposing both to exist, affects the conclusions appealed to by Dr. Geikie; and the agreement, as far as they are concerned, between theory and observation is as complete as can be. The skill with which Dr. Geikie uses his pencil to bring out the geological features of a landscape is well known: that his right hand has not lost its cunning will be evident from the two illustrations here reproduced (Figs. 2 and 3).

Reference has been repeatedly made to the proofs of enormous denudation since Tertiary times which the volcanic rocks we are dealing with furnish in lavish abundance; it has not been so often noticed that denudation has during the same interval made its effects felt on harder and more intractable rocks. But dykes furnish proof of this in a way which I believe has not been made the subject of comment. "The evidence of this denudation," says our author, "is singularly striking in such districts as that of Loch Lomond, where the difference of level between the outcrops of the dykes on the crest of the ridges and the bottom of the valley exceeds 3000 feet. It is quite obvious that, had the deep hollow of Loch Lomond lain, as it now does, in the pathway of these dykes, the molten rock, instead of ascending to the summits of the hills, would have burst out on the floor of the valley. We are therefore forced to admit that a deep glen and lake basin have in great measure been hollowed out since the time of the dyke." A point this in favour of the "gutter-theory." A. H. GREEN.

THE THEORY OF PLANETARY MOTION.[1]

IN the work the title of which is printed below, Dr. Otto Dziobek seeks to develop the theory of the motion of bodies subject to attraction according to Newton's law. The author, in his preface, draws attention to the objectionable practice of the majority of writers of the present day, of treating the subject so briefly that many students scarcely get beyond Kepler's laws in their knowledge of the theory of the solar system. He has therefore prepared a work which is intended not only as an introduction to the study of this branch of astronomy but especially for those desiring an acquaintance with the higher productions of the masters in this science.

The book is divided into three sections. The first begins with the assumption of Newton's law, and then treats of the motion of two bodies about their centre of gravity, giving the usual deductions relating to the motion of the centre of gravity, to the projections upon the three co-ordinate planes of the areas swept out by the radius-vector in a given time, and to the form of the orbit described. In determining Gauss's constant of attraction, k, the author says that the unit of length is the major axis of the earth's orbit (he doubtless means semi-axis, though the statement is repeated on the same page, and a like oversight occurs on pp. 11 and 16); and then with 1 : 354710 as the earth's mass and 365·2563835 mean solar days as the length of the sidereal year, k is found = 0·017209895. This is the value found by Gauss, and given in his "Theoria Motus." This constant has been incorporated in many tables, and any change in its value would be attended with considerable inconvenience. But since the time of Gauss more accurate values of the earth's mass and of the length of the sidereal year have been found, and consequently a more accurate value of k may be deduced. To avoid this inconvenience, the above value of k is retained, and with the new values of the earth's mass and the length of the sidereal year the unit of length is determined. This unit of length is slightly greater than the earth's mean distance from the sun, but differs from it by less than a unit of the eighth decimal.

A collection of formulæ giving the relations between the radius-vector, the mean, eccentric, and true anomalies, as in Gauss's "Theoria Motus," is added, together with the usual expansions in series of these quantities. The expressions for the expansion of the eccentric anomaly and of the radius-vector by means of Bessel's functions are also added.

We next come to the general treatment of the problem of the motion of any number of bodies projected in any manner in space, and subjected only to their mutual attractions. Here, considering n bodies, we have the usual deductions relating to the invariable plane of the system, and to the sum of the products of the mass of each body into the area described by its radius-vector. The author then proceeds to simplify the case by discussing the motion when $n = 3$, and thus the case of the celebrated problem of the three bodies. Of this the usual outline is given, together with certain special cases of the problem, the lines of the investigations of Lagrange and of Jacobi being chiefly followed. A brief historical outline of the problem, and of the chief investigations thereon from the time of Lagrange up to almost the present day, closes the first section of the work.

The second section of the book treats of the general properties of the integrals introduced in the consideration of the problem of n bodies. The investigations of Poisson and Lagrange are discussed, and the development by these writers of formulæ for the elements of the elliptic orbit of a planet is given. And here, on p. 98, we again note the oversight before referred to, viz. that of putting a = the major axis of the orbit instead of the semi-major axis. Of course such a proceeding if it were carried on throughout would have no effect upon the developments which are obtained, except on their symmetry, but the author, after mentioning that the quantity a represents the major axis, immediately proceeds to use the quantity with its usual signification, viz. the semi-major axis. The oversight occurs again on p. 112, and again in discussing the canonical constants for the elliptic motion of a planet, and again

[1] "Die mathematischen Theorien der Planeten-bewegungen." By Dr. Otto Dziobek. (Leipzig: Johann Ambrosius Barth, 1888.)

in the investigations relating to the partial differential equation of Hamilton and Jacobi, where the author deduces Lambert's important theorem concerning the relations between the time of describing an arc of the orbit, the chord of the arc, the bounding radii of the sector, and the major axis. This last-mentioned theorem for the special case of the parabola was first discovered by Euler, a point on which the late Prof. Oppolzer used to insist; the extension of the theorem for any value of the eccentricity of the orbit being due to Lambert. A short historical sketch of the matter contained in this section, referring chiefly to the labours of Lagrange, Hamilton, and Jacobi, concludes this portion of the subject, and we come to the third section of the book.

This last section of the work treats of the theory of general perturbations. Here, of course, Lagrange's theory of the variation of constants plays an important part, and we have that part fully dwelt upon by the author. The development of the disturbing function is given, and here and there a simplification in the symbols might, we think, with advantage be introduced. In the expansion of $(r_1^2 - 2r_1r_2\cos\theta + r_2^2)^{-\frac{s}{2}}$ we have given the simple expression for half the coefficient of $\cos m\theta$ in terms of Gauss's hypergeometric series, viz.—

$$r_1^{-s}\frac{s(s+2)(s+4)\dots(s+2m-2)}{2m \,.\, m!}a^m\mathrm{F}\left(\frac{s}{2}, \frac{s}{2}+m, m+1, a^2\right)$$

The secular and periodic changes in the elements of the orbit receive the usual treatment, the stability of the solar system is discussed, and also the influence upon the results of terms in the higher powers of the eccentricity and inclination.

A few pages are also devoted to a point which writers are accustomed to say never occurs in the solar system—viz. commensurability of the mean motions of two planets. The importance of the subject treated in this section induces the author to extend the limits of the historical sketch with which he has concluded the two previous sections, and to give a little more fully the history of the important theory of perturbations; and he adds, in conclusion, that the best proof of the truth of Newton's law is in the discovery of the cause "of the observed irregularities in the motion of Uranus," a cause suspected by Bouvard and by Bessel, and a problem which death prevented the latter from undertaking, but which was "von zwei anderen Astronomen Leverrier und Adams gelöst." Speaking of the latter, the author remarks that "er seine Resultate einige Monate früher dem Astronomen Airy mittheilte"; the want of a "Durchmusterung," however, placed the optical discovery of Neptune in the hands of Dr. Galle.

At the end of the book are given a few small tables chiefly Leverrier's elements of the orbits of the major planets, except for Uranus and Neptune, Newcomb's more correct values of these quantities being adopted.

We note a few misprints. On p. 5, at the bottom, referring to the rotation of the axes, "$+x$ nach $+z$" should obviously read "$+y$ nach $+z$." On p. 11, for k_2 read k^2. On p. 45, in differentiating V, a homogeneous function of degree -1, the factor z of $\frac{dV}{dz}$ is omitted. On p. 46 it might be mentioned that $M = \Sigma m$. In the copy before us, pp. 225 to 240 are omitted, and pp. 273 to 288 have been bound in their place.

Regarding the whole book, we may say that there is much that may be found in any ordinary text-book on the subject. But the author has endeavoured to do more than give a mere sketch, as writers of the present day usually do, leaving the reader to search the pages of *Crelle's Journal*, the *Comptes rendus*, or some similar publication, for important papers connected with the subject. Where these have appeared useful, they have been introduced in a modified form if necessary; and where such papers are interesting, but beyond the scope of the present work, full references are given—a practice much to be commended. The author expresses a hope that he will be able to deal later with the theory of the rotation of bodies about their centres of gravity, the figure of the earth, &c., and with the theory of the tides; and we wish him the success which the present work augurs.

R. B.

NOTES.

Dr. Alfred R. Wallace has in the press a new work on Darwinism, which aims at establishing the theory of natural selection on a firmer basis, and also deals with the various supplementary theories which have been put forth since the publication of the sixth edition of the "Origin of Species." The book will be published early next year by Messrs. Macmillan and Co.

Prof. Giard's first lecture at the Sorbonne is published in the *Revue Scientifique* (December 1). It was delivered before a large audience, and many hundreds of persons had to be content to stay at the door. The Thursday lectures of M. Giard are devoted to an historical sketch of embryology in its relation to the theory of evolution. The Saturday lectures are devoted to embryological phenomena, considered generally.

On the 19th inst. a monument of the astronomer Leverrier is to be unveiled by the French Minister of Public Instruction, in the Cour d'Honneur of the Paris Observatory. The likeness of Leverrier is said to be very striking. The statue of Arago is finished, and has been sent to the foundry. It will be situated close to the Observatory Gardens, but is not to be put in its place until after the Exhibition.

The well-known botanist, Dr. C. J. de Maximowicz, writing from St. Petersburg to Kew about Prjevalsky, whose last book we review to-day, says:—"Yes, poor Prjevalsky is dead, and I mourn for him like a brother. He was a splendid character and a highly gifted man. He died with his Expedition fitted out and ready to start. Under these circumstances, the Russian Geographical Society intends to appoint, as head of the Expedition, Colonel Pentsow, a good topographer, who has already twice been in Northern Mongolia. Lieutenant Roborofski, Prjevalsky's associate, and a very capable officer and good collector, who did the botanical work during the two last journeys, is to go also. The plan is to remain the same, perhaps with the exception of Lhassa and the investigation of Northern Tibet. But the Society will appoint this time a geologist, which it is indeed high time to do."

We learn that the Hon. John Collier has just completed a portrait of Dr. A. W. Williamson, For. Sec. R.S. This portrait, which is to commemorate the thirty-eight years of Dr. Williamson's professorial work at University College, will be presented to the College by Sir Henry Roscoe, on behalf of the subscribers, on Wednesday, December 12, at 4.30 p.m. The subscribers to this portrait will give a dinner to Dr. Williamson on the same evening at the Freemasons' Tavern.

Last Saturday, a very large meeting, convened by the Council of the Teachers' Guild of Great Britain and Ireland, was held at the rooms of the Society of Arts, Adelphi, to consider a subject which is likely soon to attract much serious attention—the organization of secondary education. The Guild numbers among its Presidents some of the most eminent authorities on higher education, as Heads of Colleges, Professors of the English, Scotch, and Irish Universities, the President of the Royal Academy, Prof. Huxley, and Mr. Mundella. Sir Philip Magnus, who presided, said that at present no public body was responsible for the secondary education of the country. There was no

department which was cognizant of the secondary schools, or of the character of the education which they provided. He insisted that it was necessary that some kind of machinery should be brought into existence for several specified objects, including (1) provision of a sufficient number of efficient secondary schools duly related to one another, and to the elementary schools beneath them, and to the Universities above them; (2) the adaptation of the instruction given in these schools to the wants and requirements of different towns and districts; (3) the registration of teachers employed in these schools; (4) the utilization of the present enormous secondary scholarship fund to provide free places in these schools, and to enable pupils from the elementary schools to receive a good secondary education, and, in certain cases, higher technical or University education; (5) the regulation and inspection of all schools in receipt of funds derived from public sources, and the recognition of all private schools that submit to such inspection; (6) the annual publication of reports showing the number and distribution of schools, the curriculum of studies, the qualifications of the teachers, the character of the teaching appliances, and the general and sanitary condition of the schools. The meeting almost unanimously passed a resolution, proposed by Prof. Gladstone, F.R.S., to the effect that an Educational Council should be called into existence, in whose hands the organization of the secondary education of the country should be placed.

THE yearly volume of the *Kew Bulletin* for 1888 is now ready. This most useful publication, as our readers are aware, contains notes on the economic products of plants which have been made the subject of particular study and investigation at Kew, and it serves as a means of communication to persons interested in botanical subjects and products in India and the colonies. In the December number there are papers on Inhambane Copal, the cultivation of rice in Bengal, silkworm thorn, Jamaica india-rubber, seedlings of sugar-cane at Barbadoes, and ramie. In the paper on seedlings of sugar-cane at Barbadoes, attention is called to the fact that Mr. J. B. Harrison, Professor of Chemistry and Agricultural Science at Barbadoes, acting in conjunction with Mr. T. R. Bovell, superintendent of Dodd's Reformatory, has been engaged during the last three years in cultural and chemical experiments with various kinds of sugar-canes. A statement sent by Prof. Harrison appears to prove, in a perfectly natural and circumstantial manner, that a few mature seeds may occasionally be produced by the sugar-cane under certain circumstances. This discovery, if it is fully confirmed, may have an important effect on the practical treatment of the question whether the saccharine qualities of the sugar-cane are capable of being improved on the same lines as those successfully adopted with regard to the beet.

WE are glad to see that a German translation of Miss A. M. Clerke's "Popular History of Astronomy during the Nineteenth Century" has just been issued. A most appreciative review of the work appears in the current number of the *Naturwissenschaftliche Wochenschrift*.

MESSRS. CASSELL AND CO. have begun to issue, in monthly parts, a new edition of their well-known "Popular Educator." This work, we need scarcely say, has been of essential service to many a student who has undertaken in earnest the task of self-education, and in its new form it may be even more useful in the future than it has been in the past. The lessons are being revised throughout, and a large portion of the work will be entirely rewritten. Among the new illustrations is a series of coloured plates, prepared for the benefit of students of ethnology, geology, astronomy, physical geography, botany, &c.

MESSRS. MACMILLAN AND BOWES, Cambridge, announce that the first volume of the "Mathematical Papers," by Prof. Arthur Cayley, will be ready in January 1889.

A LARGE number of new fluorine compounds of the rare metal vanadium have been prepared by Dr. Emil Petersen, of Copenhagen. No fluoride of vanadium has hitherto been obtained, the only compounds previously known containing fluorine and vanadium being the fluoxy-vanadates of Baker, and a few other oxy-compounds, recently described by Piccini and Giorgio, which latter appear to have been independently obtained by Petersen. The most important of the new compounds is sesquifluoride of vanadium itself, V_2F_6, which has been obtained in fine large rhombohedrons of a dark-green colour, containing six molecules of water of crystallization, and very soluble in water. Next in importance are two probably isomorphous double fluorides of vanadium with potassium and ammonium, $V_2F_6 . 4KF . 2H_2O$, and $V_2F_6 . 4NH_4F . 2H_2O$; the former was obtained in the form of a bright-green crystalline precipitate, and the latter in brilliant emerald-green and tolerably large octahedra. Besides this compound with ammonium fluoride, another, of the composition $V_2F_6 . 6NH_4F$, was isolated in small grass-green, regular octahedra; this salt is especially interesting as being isomorphous with the analogous chromium and titanium compounds. To complete the isomorphous group, Dr. Petersen has also prepared the aluminium compound $Al_2F_6 . 6NH_4F$. Another interesting pair of isomorphous salts are the compounds $V_2F6 . 2CoF_2 . 14H_2O$ and $V_2F6 . 2NiF_2 . 14H_2O$, the former of which was obtained in dark-green, and the latter in grass-green monoclinic prisms. The remarkable similarity of the sesqui-vanadium and sesqui-chromium compounds is again beautifully shown by the fact that two precisely analogous salts containing cobalt or nickel and chromium instead of vanadium were successfully prepared, containing also fourteen molecules of water of crystallization and crystallizing in green monoclinic prisms. In addition to these important double fluorides of vanadium sesqui-fluoride, a number of oxy-fluorides, derived from vanadic anhydride, V_2O_5, and analogous to the well-known oxychlorides of phosphorus, have also been obtained in combination with alkaline fluorides. The two most important of these appear to be the oxyfluorides, $VOF_3 . 2KF$ and $VO_2F . 2KF$, the latter forming beautiful golden-yellow hexagonal prisms. This preliminary communication of Dr. Petersen, which will be found in the current *Berichte*, just received, forms a rich addition to our information concerning the element vanadium, and the details of the preparation of these well-crystallized salts, a small selection of which only have been described above, will be looked forward to with considerable interest.

THE new Ethnological Museum in Sydney, nominally opened last January, has now really been made accessible to the Australian public. The collection, which includes a large number of weapons and implements obtained from aboriginal races, is described by the *Sydney Daily Telegraph* as one "of absorbing interest."

WE have received Nos. 2 and 3 of vol. lvii. part 2, of the Journal of the Asiatic Society of Bengal. They contain notes on Indian Rhynchota, by E. T. Atkinson; a paper on the tornado which occurred at Dacca on April 7, 1888, by A. Pedler and A. Crombie; notes on the Amphipoda of Indian waters, by G. M. Giles; a paper on *Eupetaurus*, a new form of flying squirrel from Kashmir, by O. Thomas; and notes on Indian Chiroptera, by W. T. Blanford, F.R.S.

MR. THOMAS's account of the new form of flying squirrel from Kashmir, is very interesting. In connection with its dental evolution Mr. Thomas says it would be advisable for naturalists and sportsmen in Kashmir to notice what its food is, as compared with that of other squirrels. Judged from its blunt claws, it probably frequents rocks and precipices rather than trees, and it is therefore possible that its ordinary food may consist of lichens,

mosses, and other rock-loving plants, which, by being mixed with sand and particles of rock, would necessitate the development of such long lasting molars as it is remarkable for possessing. Additional specimens of *Eupetaurus* would be most valuable for scientific examination, especially if of different ages; and Mr. Thomas expresses a hope that some of the many British sportsmen who annually visit Kashmir will help to enrich either the Indian Museum in Calcutta, or the National Museum at home, with examples of this, the latest addition to the mammal fauna of our Indian Empire.

In the new number of the *Zoologist* Mr. T. Southwell has an interesting article on Pallas's sand grouse in Norfolk. Speaking of a large flock which Mr. Wood, of Morston, had under his close observation for some months, Mr. Southwell says that they frequented the same fields with great regularity; their favourite feeding-place being a large clover layer, from which, if disturbed, they flew across to some adjacent turnip-fields, choosing the bare patches for their feeding-ground. Here they spread over a circle of some 30 or 40 yards, separating, and diligently searching the ground until they appeared to have exhausted the food in that particular locality, when they all rose together and repaired to a fresh spot, which they exhausted in like manner. At stated times they departed for the salt marshes adjacent. The bird is usually extremely shy, but not always. Mr. A. Napier was shooting on the Holkham sand-hills with Lord Leicester and party, on October 13, when they met with a flock of about thirty-five. "A single bird," says Mr. Napier, "which I came upon, I felt convinced must have had either a nest or young. When first I saw it, it fluttered along in front of me just like a partridge with young. It was so tame that I called Lord Leicester and the others up to see it, and it did not fly up until we had approached to within 3 or 4 yards of it. At first I thought it must have been a wounded bird, but I do not think so now, for it flew away very strongly, calling out most lustily. Its action reminded me very much of the turtle-dove." Other incidents of a like kind are recorded by Mr. Southwell. On August 5 the gardener at Shernbourne Hall came to Mr. Parsons to say that a sand grouse was running about on the lawn. Mr. Parsons went out to catch it, thinking his son's pinioned bird had escaped. On being approached, the bird "ran and skulked in a little ditch," and did not rise till Mr. Parsons was about to put his hand on it, when it flew away "quite strong." Another, now in Mr. Gurney's aviary at Northrepps, was found, on October 31, floundering in a wet ditch at Suffield, and taken by hand.

We learn from the *Canadian Record of Science* (vol. iii. No. 3) that in June 1887 a small collection of graptolites was obtained by Dr. G. M. Dawson, on Dease River, in the extreme northern and inland portion of British Columbia, about lat. 59° 45', long. 129°. These fossils were derived from certain dark-coloured, carbonaceous and often calcareous shales, which, in association with quartzites and other rocks, characterize a considerable area of the lower part of the Dease, as well as the Liard River, above the confluence. In 1886 a similar small collection was obtained by Mr. G. R. McConnell, near the line of the Canadian Pacific Railway, in the Kicking Horse (Wapta) Pass. No other locality in the western portion of the Dominion has yet been found to yield graptolites. Prof. Lapworth, to whom Dr. Dawson's collection has been transmitted, thinks that the graptolite-bearing rocks are clearly of about Middle Ordovician age. They contain forms he would refer to the second or Black River Trenton period; *i.e.* they are newer than the Point Lévis series, and older than the Hudson and Utica groups. The association of forms, he says, is such as we find in Britain and Western Europe, in the passage beds between the Llandeilo and Caradoc Limestones.

The following are the lecture arrangements of the Royal Institution before Easter:—Prof. Dewar, six lectures (adapted to a juvenile auditory) on clouds and cloudland; Prof. G. J. Romanes, twelve lectures constituting the second part of a course on before and after Darwin (the evidences of organic evolution and the theory of natural selection); Prof. J. W. Judd, four lectures on the metamorphoses of minerals; Dr. Sidney Martin, four lectures on the poisonous action of albuminoid bodies, including those formed in digestion; Prof. J. H. Middleton, four lectures on houses and their decoration from the classical to the mediæval period; Prof. Ernst Pauer, four lectures on the characters of the great composers and the characteristics of their works (with illustrations on the pianoforte); and eight lectures by the Right Hon. Lord Rayleigh, on experimental optics (polarization; the wave theory). The Friday evening meetings will begin on January 25, when a discourse will be given by Prof. G. H. Darwin; succeeding discourses will probably be given by Prof. W. C. McIntosh, Sir William Thomson, Prof. A. W. Rücker, Mr. Harold Crichton Browne, Prof. Oliver Lodge, Prof. Archibald Geikie, the Rev. Alfred Ainger, the Right Hon. Lord Rayleigh, and other gentlemen.

The Russian naturalist, M. K. Nossilow, has been making geological investigations in Nova Zembla, and has discovered traces of gold.

Prof. Oliver J. Lodge writes to us as follows about his letter on the "Velocity of Sound" (Nature, November 22, p. 79):—"In equation (6), $U + v$ should, strictly, be $-U + v$, because the sign of U has changed with its signification. Equation (7) is therefore wrong. In the paragraph between equations (3) and (4), the words 'condensation' and 'rarefaction' should be transposed."

The additions to the Zoological Society's Gardens during the past week include two Squirrel Monkeys (*Chrysothrix sciurea*) from Guiana, presented by Master H. B. Young; a Silvery Gibbon (*Hylobates leuciscus* ♂) from Burmah, presented by Captain D. L. de la Chevois; a Pig-tailed Monkey (*Macacus nemestrinus* ♀) from Java, presented by Mr. W. Merryweather; a Polecat (*Mustela putorius*), British, presented by Mr. F. D. Lea Smith, F.Z.S.; a Raven (*Corvus corax*), British, presented by Mr. C. Petrzywalski; a Sparrow Hawk (*Accipiter nisus*), British, presented by Mr. G. Skegg; two Barn Owls (*Strix flammea*), British, presented by Mr. E. Hart, F.Z.S.; a Lion Marmoset (*Hapale rosalia*) from Brazil, deposited; a Blue-cheeked Barbet (*Megalæma asiatica*) from India, a Golden-crowned Conure (*Conurus aureus*) from South-East Brazil, a Golden-winged Parrakeet (*Brotogerys chrysopterus*) from the Amazons, purchased.

OUR ASTRONOMICAL COLUMN.

Stonyhurst College Observatory.—The Report of this Observatory for 1887, which has been recently published, is of the usual character, giving the results of the magnetic and meteorological observations for the year. The daily areas of the spots observed upon the sun during 1886 and 1887, expressed in millionths of the sun's visible hemisphere, are also given in both tabular and graphical form. The latter shows in a very striking manner the remarkable depression in spot-activity which marked the seven months from the end of September 1886 to the end of April 1887, and the regular series of gentle undulations which succeeded it. A note on the "Upper Glows in 1887" records that the white haze round the sun, and the pink "fore" and "after" glows consequent upon the Krakatão explosion, were still observed occasionally in 1887, but more feebly and less frequently than in 1886.

The Hopkins Observatory.—The little Observatory of this name attached to Williams College, Mass., is the oldest public Observatory in the United States, and during the past summer the jubilee of its dedication was duly celebrated. This interesting commemoration was made the occasion for the delivery of a discourse by Prof. T. H. Safford, Field Memorial Professor of Astronomy at Williams College, on the development of astro-

nomy in the United States, with especial reference to its earliest days; indeed Prof. Safford in his address went back not merely to the surveying work of Mason and Dixon, but even glanced lightly at the history of the institution where the former had been trained—Greenwich Observatory. The Hopkins Observatory was the work of the two brothers, President Mark Hopkins and Prof. Albert Hopkins, the latter of whom worked with his own hands at the erection of the building. Both were gifted men, and of advanced ideas, and their purpose in erecting the Observatory seems to have been the hope that the practical work of observing would increase their students' interest in the science, and develop their powers in fresh directions. It is still used by the students for occasional star-gazing, but for scientific purposes it has been superseded of late years by the meridian instrument of the "Field Memorial Observatory." The Hopkins Observatory was soon followed by others, at West Point, at Harvard College, at Washington, and other places, but though there had been previously one or two private observatories, and also a few telescopes in the possession of some public bodies, as, for example, at Yale College, yet until 1838 no permanent structure had been erected for any public observatory, so that the credit of being the pioneer of the long and distinguished succession of American Observatories belongs to the little building erected by the energy of Prof. Hopkins.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 *DECEMBER* 9-15.

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on December 9

Sun rises, 7h. 56m.; souths, 11h. 52m. 48·6s.; sets, 15h. 49m.: right asc. on meridian, 17h. 7·4m.; decl. 22° 54′ S. Sidereal Time at Sunset, 21h. 4m.

Moon (at First Quarter December 10, 7h.) rises, 12h. 36m.; souths 17h. 43m.; sets, 23h. 0m.: right asc. on meridian, 22h. 58·8m.; decl. 10° 51′ S.

Planet.	Rises.		Souths.		Sets.		Right asc. and declination on meridian.				
	h.	m.	h.	m.	h.	m.	h.	m.	°	′

GEOGRAPHICAL NOTES.

The rumour brought from the Cameroons as to the position of Mr. Stanley is too vague to be of much value. He is said to be behind "the Oil Rivers and the Niger," annexing territories wholesale for the British Crown. He may possibly enough be coming out in this direction. If so, he must have been with Emin, for it is inconceivable that, if able to get so far, he would fail in the chief object of his mission. If he has been with Emin, that must have been some time ago, and surely some word of it would have oozed out. We should not be surprised to find Mr. Stanley coming out by the West Coast; it would be quite in accordance with the purpose he had of settling, if possible, the problem of the Shari and Wellé. He may have sought to discover the parting that separates the basins of Lake Chad and the Congo, and the upper waters of the Binué. If he has really been on the Binué, we should have expected some definite news from the officials of the Royal Niger Company.

Though Mr. Joseph Thomson was summoned home from Morocco to lead an expedition to Emin Pasha, we regret to learn that the British East African Company are hesitating to carry out the purpose they entertained when they telegraphed for Mr. Thomson.

M. Rabot, in describing to the Paris Geographical Society the results of a visit which he recently made to Western Greenland, states the following conclusions:—In comparing the inland ice of Greenland with the glaciers of Lapland, it appears to him absolutely certain that the latter are nothing more than inland ice in miniature. The Lapland glaciers are simply the remains of the Glacial period in Scandinavia, which have persisted to the present time owing to special circumstances. The great glacier of Jakobshavn, on the west coast of Greenland, has been advancing during the last few years. Its front edge is at present 3 kilometres in advance of the point where it was seen by Lieut. Hammer in 1878. The drift ice of the south-west coast transports only a very small quantity of material. M. Rabot saw only one piece among fifty or sixty which bore debris of detritic origin, while traversing pack-ice 60 miles broad. Only one piece was black with earth.

In connection with Dr. Nansen's journey across Greenland, a paper by Dr. Rink, in No. 137 of the *Zeitschrift* of the Berlin Geographical Society, is of interest. Dr. Rink discusses the data which have been obtained by the various Danish Expeditions to Greenland, as well as by the parties which at different times have attempted to cross the land. He enters in some detail into the general subject of glaciation, and the relation between glaciers and icebergs. He seems to be of opinion that the ice of Greenland is shrinking, as he points out that there are evidences that at one time the ice covered the whole of the coastland, which is at present free, as well as the peninsulas and islands in its vicinity.

The same number contains a paper, by Dr. von Danckelmann, on the altitudes of the country at the junction of the Kassai and Congo.

In No. 8 of the *Verhandlungen* of the Berlin Geographical Society, Dr. Schweinfurth gives a useful sketch of his explorations in Egypt during the past fifteen years. In a letter to the President, in the same number, Dr. Hettner describes his observations on the Peruvian coast between Mollendo and Arequipa.

NOTES ON METEORITES.[1]

VI.

COMETS ARE METEOR-SWARMS WHICH HAVE ENTERED THE SOLAR SYSTEM SOME TIME OR OTHER.

THESE swarms, then, are comets. The final demonstration, as we have seen, we owe to the labours of Newton, Adams, and Schiaparelli chiefly. But long before their time the connection between shooting-stars (and even meteorites) and comets had been suspected on various grounds.[2]

Many shooting-stars pass through the air with a trail. This appearance is certainly suggestive of a very rapid comet. Hence, perhaps, it was that such an appendage, often noticed in the case of bright meteors, was sometimes in ancient records described as a comet. It is known that Cardano described as a comet the great meteor from which fell 1200 stones on the territory of Crema on September 4, 1511.[3]

Not only, as we have seen, Kepler (1600) regarded shooting-stars as akin in nature to meteorites, but he held that both had the same origin as comets:—"Falling stars are composed of inflammatory viscous materials. Some of them disappear during their fall, while others indeed fall to the earth, drawn by their own weight. Nor, indeed, is it improbable that they have been formed into globes from feculent materials mixed with the ethereal air itself, and thrown from the ethereal region in a straight line through the air like very small comets, the cause of the motion of both being hidden."[4]

Halley (1700) though he thought that the phenomenon of shooting-stars[5] was produced by a material disseminated through celestial space falling upon the sun and meeting the earth in its passage, did not associate it with cometary phenomena; but Maskelyne (1765) held that meteors were of celestial origin, and was inclined to assimilate them to comets. He wrote as follows in a letter to the Abbé Cesaris, the astronomer at Milan, about December 12, 1783:—"Freely accept, I pray you, this map, which I have lately published in order to stir up learned men rather than the unlearned, to observe more keenly the phenomena called fire-balls. In all probability they will turn out to be comets. . . ."[6]

To Chladni belongs the credit of having broached the theory which modern observations have established.

We have already seen that Chladni formulated the view, in 1794, that space is filled with matter. In 1819 he extended it by stating that both shooting-stars, meteorites, and comets were but different manifestations of it.[7]

Chladni made a step in this matter of which, as pointed out by Schiaparelli, only to-day are we able to appreciate the importance. In suggesting the cosmical hypothesis, he regarded two possible cases: either the meteors were formed of masses of independent materials which had never formed part of the larger celestial bodies, or they are the result of the destruction of a celestial body previously existing. Chladni held the second hypothesis as possible. but held to the first as more probable. He stated that we could not doubt the existence in the celestial space of small bodies endowed with movement, which are now and then visible by passing before the sun.

He held, therefore, that the small masses which appear under the forms of bolides and falling stars do not differ essentially from comets. It is also probable, he says, that comets consist of clouds composed in great part of masses of vapour and dust, which are kept together by mutual attraction. That this attraction is not enough to sensibly disturb the planetary movements is a proof of the exceeding tenuity and dispersion of the materials in such clouds, through which, however large, it is possible, to observe the fixed stars.[8]

In 1839 the Abbé Raillard suggested a connection between luminous meteors and comets and the aurora,[9] and Dr. Forster noted that the years marked by the appearance of a large comet are remarkable also for the abundance of falling stars, especially of white ones.[1]

Perhaps the first to give a more solid support to the cometary theory of falling stars on geometric grounds was Boguslawski, who conceived the idea of representing by means of parabolas the apparent orbits observed in some of the August meteors of 1837.[2]

For the next important advance in thought upon this subject we have to come down to 1858, in which year Baron Reichenbach published a most important memoir[3] attacking the question from an entirely new point of view. Reichenbach, accepting as proven by the then knowledge the most intimate connection between meteorites and falling stars, reasoned in the following manner, that both were connected with comets. He first recapitulated the facts then accepted with regard to comets:—

(1) Comets, both tail and nucleus are transparent.

(2) Light is transmitted through comets without refraction; hence the cometary substance can be neither gaseous nor liquid.

(3) The light is polarized, and therefore borrowed from the sun.

(4) Comets have no phases like those of moon and planets.

(5) They exercise no perturbing influences.

(6) Donati's comet (which was then visible) in its details and its contour is changing every day—according to Piazzi, almost hourly.

(7) The density of a comet is extremely small.

(8) The absolute mass is sometimes small (von Littrow having calculated very small comets, tail and all, as scarcely reaching 8 pounds).

From these data the following conclusions might be drawn:—

(1) That a comet's tail must consist of a swarm of extremely small but solid particles, therefore granules.

(2) That every granule is far away from its neighbour—in feet, so far that a ray of light may have an uninterrupted course through the swarm.

(3) That these granules, suspended in space, move freely and yield to outer and inner agencies—agglomerate, condense, or expand; that a comet's nucleus, where one is present, is nothing else than such an agglomeration of loose substances consisting of particles.

Hence we must picture a comet as a loose, transparent, illuminated, free-moving swarm of small solid granules suspended in empty space.

The next step in Reichenbach's reasoning was to show that meteorites (of which he had a profound knowledge) were really composed of granules.

He pointed out that these granules (since called chondroi) formed really the characteristic structure both of irons and stones, so that both orders were chiefly aggregates of chondroi—stony ones in iron meteorites, iron ones in stony meteorites.

In some irons, such as Zacatecas, they exist as big as walnuts, firmly adherent, but they can be separated; inside these are balls of troilite, often firmly embedded, so that on breaking the meteorite they will divide, but in other cases so loose that they fall out, and they are smooth enough to roll off a table.

Sometimes chondroi have smaller ones sprinkled in them, sometimes dark chondroi have white earthy kernels.

In some cases these chondroi are so plentiful as to form nearly the whole mass of the meteorite. They are often perfectly round, but not always, and they are often so loose that they tumble out and leave an empty smooth spherical cavity.

The stones chiefly consist of such chondroi and their *débris*.

He adds that each magnesic chondros "is an independent crystallized individual—it is a stranger in the meteorite. Every chondros was once a complete, independent, though minute meteorite. It is embedded like a shell in limestone. Millions of years may have passed between the formation of the spherule and its embeddal."

He then goes on to remark that the chondroi of meteorites indicate a condensation of innumerable bodies such as we see must exist in the case of comets; further, that they have been formed in a state of unrest and impact from all sides. Many meteorites are true breccias; they have *many times* suffered mechanical violence. He then shows that in comets we have precisely the conditions where such forces could operate, and

hence arrives at the view that "comets and meteorites may be nothing else but one and the same phenomenon." [1]

This was in 1858, eight years before Schiaparelli's discovery. Newton, as we have seen, referred the comet of 1862 to the largest meteorite in the August swarm.

We may assume from the work which has already been done that Reichenbach's view is more probably the true one, and that the head of a comet is merely the denser part of the swarm. Whether that denser part is at the end or at the beginning of the long line to which reference has been made, it does not very much matter, but where that is there we shall have the appearance of a comet presented to us in the heavens. That being so, we are able to apply everything that we have learned about comets to the movements of meteorites in space ; in the case of meteors and falling stars we were limited to what took place in our own air.

The Appearances presented by Comets away from the Sun.

When a comet first becomes visible, it appears in the telescope as a round misty body, and moves very slowly in consequence of its still great distance from the sun. At this time, too, its light is very feeble. Its appearance under these con-

Fig. 12.—A comet near aphelion.

ditions strikingly resembles that of a nebula, and in fact comets have often thus been mistaken for nebulæ.

Occasionally the appearance put on is that of a planetary nebula in small telescopes and a globular one in larger ones.

Fig. 13.—The Pons-Brooks comet, January 13, 1834 (Thollon).

The globular form, after a time, gives way, and the concentration of light is now a star-like concentration at one end of an elliptic patch.

[1] For this analysis of a part of Reichenbach's memoir, I am indebted to my friend Mr. L. Fletcher, of the British Museum.

In the next phase, both the star-like object and the elliptic patch lengthen, and the appearance becomes more like what is ordinarily recognized as a comet.

As the comet approaches nearer the earth, so that observations of its several portions may be seen, we get a still greater differentiation of the phenomena.

Fig. 14.—The first beginnings of a tail.

Fig. 16, which is a representation of Donati's comet as it appeared in 1858, will serve to illustrate the main characteristics of comets. The brighter part is called the *head* or *coma*, and sometimes there is within this a still brighter and smaller portion called the *nucleus*. The *tail* is the dimmer part radiating from the head,

Fig. 15.—The lower portion represents the elongation of the star-like luminosity ; the upper one. the concomitant extension of the whole comet (Comet 1882 October 25, Seabroke).

and this varies greatly in different comets ; it may be long or short, straight or curved, single, double, or multiple. The comet of 1744 had six tails, that of 1823 two. In others the tail is entirely absent. The tail of the comet of 1861 was 20,000,000 miles in length, and that of the comet of 1843 was 112,000,000 miles long.

Both head and tail are so transparent that all but the faintest stars are easily seen through them. The star Arcturus was seen through the tail of Donati's comet in 1858 at a place where it was 90,000 miles in diameter.

As a comet approaches the sun, its velocity, like that of the planets, increases, and it gradually gets hotter and gives out more light.

When the comet gets sufficiently hot, *aigrettes* or *jets* make their appearance ; these are so called because they seem to shoot

Fig. 16.—Donati's comet (general view).

out from the nucleus like sparks shoot out from a squib. The jets rapidly change their positions and directions, and the tail is formed, apparently at the expense of the matter of which the head was in the first instance built up. The tail is always turned from the sun, whether the comet be approaching or receding.

Drawings of a comet, as seen at different times, show how the jets vary in appearance and direction. Instead of jets, some comets present phenomena of a very different character, called envelopes, which are thrown off concentrically from the nucleus.

Fig. 17.—Comet with single nucleus (Cruls's comet, 1882, Riccò).

These are among the chief physical peculiarities about the heads of comets; and we see at once that we have something perfectly distinct from the planets, and that some comets are at first sight different from others. The envelopes have been observed to rise from the nucleus with perfect and exquisite regularity in exactly the same way that the jets swing backwards and forwards.

The enormous effect produced by a near approach to the sun may be gathered from the fact that the comet of 1680, at its perihelion passage, while travelling at the rate of 1,200,000 miles an hour, in two days shot out a tail 60,000,000 miles in length.

We must now enter somewhat more into details with regard to some of these cometary characteristics.

First of all, it must be pointed out that the meteoritic swarms

Fig. 18.—Nucleus surrounded by ellipsoidal head (Comet 1882 October 25, in Washington refractor).

are not always single, for in some comets the nuclei are double or triple.

In the case of single nuclei the nucleus may be the origin, and lie in the brighter region the extension of which forms the

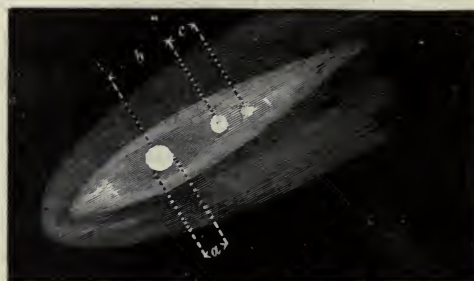

Fig. 19.—Compound nucleus (same comet November 5).

tail. But this is not invariable: the nucleus may be caught forming part of an elliptic head (Fig. 18) before any very great extension of the tail begins to take place, owing to reasons which will be stated further on.

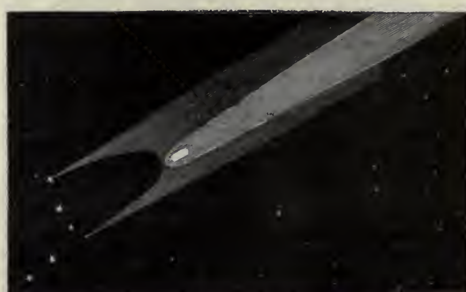

Fig. 20.—Commander Sampson's sketch of the great comet, 1882, October 10.

In the case of double or multiple nuclei we have a clear indication of the existence of more than one chief meteoritic swarm, whether they be enveloped in the same atmosphere or give rise to the same tail (Fig. 19). But it would seem that, in

some cases, different nuclei may give rise to separate tails; such would seem a possible explanation of Commander Sampson's observation of the comet of 1882 (Fig. 20).

J. NORMAN LOCKYER.

(*To be continued.*)

THE ANNIVERSARY MEETING OF THE ROYAL SOCIETY.

THE anniversary meeting of the Royal Society was held on Friday last, St. Andrew's Day. The President read the anniversary address—a copy of which has not yet reached us—and presented the medals. Prof. Huxley received the Copley Medal, and Mr. Crookes the Davy Medal in person. Prof. Osborne Reynolds was also present to receive one of the Royal Medals. The other Royal Medal was received on behalf of Baron von Mueller by Sir Graham Berry, Agent-General for Victoria, and the Rumford Medal, which had been awarded to Prof. Tacchini, was received on his behalf by the Chevalier Catalani, the *Chargé d'Affaires* at the Italian Embassy. The Society next proceeded to elect the officers and Council for the ensuing year. The selected names we have already published.

In the evening about 175 Fellows and guests dined together at Willis's Rooms. Among the guests were eminent representatives of the English Government, of foreign nations, and of art and literature. Sir Frederick Leighton, in proposing "The Royal Society," said:—

"A great honour is done to me in intrusting to my hands the toast which I have risen to propose, for it is the toast round which the chief sympathies of those who sit at this table are centred, be they hosts or be they guests—namely, prosperity to that ancient and honoured body, the Royal Society. It is, indeed, a toast favoured in this—that no inadequacy of presentment could rob it of your warm reception, but it is one, also, which, in one sense, the individual now before you is so little fitted to propose that I could almost suspect you, Sir, of a little prompting of humour in your selection. I do not mean because the bodies with which you and I have respectively the honour to be connected are now, in Piccadilly, as they were in former days in Somerset House, next-door neighbours, and because it is not habitually to one's next-door neighbour that one looks in life for a kind word, but on this other and more cogent ground—that the subject on which you bid me speak is one in regard to which I am entirely ignorant, and that my attitude is therefore not free from ludicrous aspects in the face of a body to which grasp and accuracy of knowledge is the one thing needful, and precision of statement the first duty of man; and this, Sir, certainly not least in the day of your headship. And yet, on closer view, it is not knowledge, perhaps, that you require of the proposer of this toast so much as respectful sympathy; and that you find in me to the full. No, gentlemen, you do not demand in me knowledge beyond that of the average ignoramus who watches you in wonder as you sound with divining eyes the realms of the heavens above and of the earth beneath and of the water under the earth, and lay bare before us the very beat of the life-pulse of Nature. You demand in me, I say, rather, some sympathetic sense of your magnificent missions, some adhesion to the faith that you profess, and for these you do not look to me in vain. It happens to me, Mr. President, from time to time to have to acknowledge words of recognition of the services of the great institution to which I am bound in a like capacity with your own; and, knowing how earnestly that body is bent on the worthy discharge of an arduous task, such words are deeply grateful to me, but in every such case I see in my inner mind, behind and above the institution which I serve, the sweet and serene countenance of our divine mistress—of Art herself; and so, also, in offering this toast to the acclamation of your guests and to the acceptance of your flock, I am thinking less of the noble services of your renowned Society, less of the many names which are its high adornment at this time and our country's pride, than of your mistress beneficent and supreme, the scatterer of darkness—Science. All of us walk in the daylight of her illumination, the humblest layman can bear witness to her, and the most ignorant concerning the paths she treads may yet not unbecomingly declare his gratitude to her ministers, and express, as I now express, the hope that they and their successors may in the bond of this constituted brotherhood long continue to tend the flame and feed the increasing splendour of her sacred inextinguishable lamp."

The President of the Royal Society responded in a short speech, in which he compared the Royal Society to a wave of light moving onward through space, conveying intelligence from one portion of the universe to another far-distant portion. The molecules which it set in motion had but a brief existence, but the wave moved ever onward.

SCIENTIFIC SERIALS.

THE *Journal of Botany* is still largely occupied with the discussion of points connected with botanical nomenclature, in which English, American, and Genevan botanists take part. The October number contains also a description of a new genus of Berberidaceæ by the Japanese botanist Tokutaro Ito.—In the November number are papers on the genus *Carex*, by Mr. L. H Bailey; on Ferns from West Borneo, by Mr. J. G. Baker; on South Derbyshire plants, by Rev. W. R. Linton; and on the Desmids of Maine, by Mr. W. West. Mr. W. H. Beeby records the interesting fact that of the two very nearly allied s ecies of valerian, *Valeriana Mikanii* and *sambucifolia*, one is very attractive to cats, while to the other they are quite indifferent.

IN the *Botanical Gazette* for September, Mr. C. Robertson completes his essay on zygomorphy and its causes, summing up the results of his observations. The remainder of the number is largely occupied by abstracts of botanical papers read at the Cleveland meeting of the American Association for the Advancement of Science.—In the October number are two important anatomical papers, by Miss Emily L. Gregory on the development of cork-wings on certain trees, and an illustrated one by Mr. W. H. Evans on the stem of Ephedra. Mr. G. Vasey contributes an interesting article on the characteristic vegetation of the North American desert.

THE number of the *Nuovo Giornale Botanico Italiano* for October 1888 is entirely occupied by reports of the papers read before the annual meeting of the Botanical Society of Italy held at Florence in September, many of which are of considerable interest.—Sig. C. Massolongo describes the germination of the spores of three new species of Sphæropsideæ—*Phyllosticta Bizzozeriana*, *P. Aristolochiæ* and *Phoma Orobanches*. He maintains that the only difference between pycnidia and spermogonia is that the sporules (stylospores) contained in the former are capable of germinating directly, while those formed in the latter (spermatia) have no such power.—Sig. A. N. Berlese adds to the very numerous fungus-parasites of the vine two new ones, *Greeneria fuliginea*, S. et V., and *Ascochyta rufo-maculans*, Berk.—Sig. G. Gasperini has investigated the nature of the organisms which bring about the fermentation of the palm-wine known to the Arabs under the name of "*legbi*." He finds it to be due to *Saccharomyces cerevisiæ*, which is always accompanied by *Bacillus subtilis*. On the surface is also commonly found a pellicle of *Saccharomyces Mycoderma*.—Prof. A. Borzi describes a new species and genus of Ascomycetes—*Eremothecium Cymbalariæ*, found on half-ripe capsules of *Linaria Cymbalaria*.—The little-known germination of the seeds of the water-lily, *Euryale ferox*, is described by Sig. G. Arcangeli, the chief peculiarity being the almost entire suppression of the elongation of the radicle.—Prof. L. Macchiati claims to have discovered an entirely new substance, which he calls *xanthophyllidrin*, as a constituent of the green colouring-matter of plants. It is crystallizable, and altogether distinct from xanthophyll and from the pigment of yellow petals.—Prof. A. Borzi describes the mode in which *xerotropism* displays itself in some ferns—*Ceterach officinarum*, *Notochlæna Marantæ*, *Asplenium Trichomanes*, and several species of *Cheilanthes*; understanding by this term the mechanical contrivances by which an organ protects itself against excessive desiccation.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 22.—"The Waves on a rotating Liquid Spheroid of finite Ellipticity." By G. H. Bryan, B.A. Communicated by Prof. G. H. Darwin.

The hydrodynamical problem of finding the waves or oscillations on a gravitating mass of liquid which when undisturbed is rotating as if rigid with finite angular velocity in the form of an ellipsoid or spheroid, was first successfully attacked by M. Poincaré in 1885.

Poincaré's analysis, however, did not appear to admit of any definite conclusions being formed as to the nature and frequencies of the various periodic free waves. The present paper contains an application of Poincaré's methods to the simpler case when the fluid ellipsoid is one of revolution (Maclaurin's spheroid). The solution is effected by the use of the ordinary tesseral or zonal harmonics applicable to the fluid spheroid and the auxiliary spheroid required in solving the differential equation.

Denoting by κ the ratio of the frequency of the free waves to twice the frequency of rotation of the liquid about its axis, the values of κ are the roots of a rational algebraic equation, and depend only on the eccentricity of the spheroid as well as the degree and rank of the harmonic, while the number of different free waves depends on the degree of the equation in κ. At any instant the height of the disturbance at any point of the surface is proportional to the corresponding surface harmonic on the spheroid multiplied by the central perpendicular on the tangent plane, and is of the same form for all waves determined by harmonics of any given degree and rank, whatever be their frequency, but the motions of the fluid particles in the interior will differ in nature in every case.

Taking first the case of zonal harmonics of the nth degree, we find that according as n is even or odd there will be $\frac{1}{2}n$ or $\frac{1}{2}(n + 1)$, different periodic motions of the liquid. These are essentially oscillatory in character, and symmetrical about the axis of the spheroid. Taking next the tesseral harmonics of degree n and rank s, we find that they determine $n - s + 2$ periodic small motions. These are essentially tidal waves rotating with various angular velocities about the axis of the spheroid, the angular velocities of those rotating in opposite directions being in general different.

With regard to the question of stability, the author shows that in the present problem, in which the liquid forming the spheroid is supposed perfect, the criteria are entirely different from the conditions of secular stability obtained by Poincaré for the case when the liquid possesses any amount of viscosity, which latter depend on the energy being a minimum. In fact for a disturbance initially determined by any harmonic (provided that it is symmetrical with respect to the equatorial plane, since for unsymmetrical displacements the spheroid cannot be unstable), the limits of eccentricity consistent with stability are wider for a perfect liquid spheroid than for one possessing any viscosity. If we assume that the disturbed surface initially becomes ellipsoidal, the conditions of stability found by the methods of this paper agree with those of Riemann.

Finally the methods of treating forced tides are further discussed.

The general cases of a "semi-diurnal" forced tide or of permanent deformations due to constant disturbing forces are mentioned in connection with some peculiarities they present, and the paper concludes with examples of the determination of the forced tides due to the presence of an attracting mass, first when the latter moves in any orbit about the spheroid, secondly when it rotates uniformly about the spheroid in its equatorial plane.

The effects of such a body in destroying the equilibrium of the spheroid when the forced tide coincides with one of the free tides are then considered.

Anthropological Institute, November 13.—Francis Galton, F.R.S., President, in the chair.—Dr. E. B. Tylor read a paper on a method of investigating the development of institutions applied to laws of marriage and descent. With the view of applying direct numerical methods to anthropology, the author had compiled schedules of the systems of marriage and descent among some 350 peoples of the world, so as to ascertain, by means of a "method of adhesions," how far each rule co-exists or not with other rules, and what have been the directions of development from one rule to another. As a first test of the results to be obtained by this means, Dr. Tylor first examined the barbaric custom which forbids the husband and his wife's parents (though on a friendly footing) to speak or look at one another, or mention one another's names. Some seventy peoples practise this or the converse custom of the wife and her husbands relatives being obliged ceremonially to "cut" one another. On classifying the marriage rules of mankind, a marked distinction is found to lie between those peoples whose custom is for the husband to reside with his wife's family and those where he removes her to his own home. It appears that the avoidance custom between the husband and the wife's family belongs preponderantly (in fourteen cases, as compared with eight computed as likely to happen by chance) to the group of cases where the husband goes to live with the wife's family. This implies a causal connection between the customs of avoidance and residence, suggesting as a reason that the husband, being an interloper in the wife's family, must be treated as a stranger; to use an English idiom expressing the situation, he is not "recognized." Other varieties of the custom show similar preponderant adhesions. Another custom, here called *teknonymy*, or naming the parent from the child, prevails among more than thirty peoples; as an example was mentioned the name of Ra-mary, or Father of Mary, by which Moffat was generally known in Africa. This custom proves on examination to adhere closely to those of residence and avoidance, the three occurring together among eleven peoples—that is, more than six times as often as might be expected to happen by chance concurrence. Their connection finds satisfactory explanation in the accounts given of the Cree Indians of Canada, where the husband lives in his wife's house, but never speaks to his parents-in-law till his first child is born; this alters the whole situation, for though the father is not a member of the family, his child is, and so confers on him the status of "Father of So-and-so," which becomes his name, the whole being then brought to a logical conclusion by the family ceasing to cut him. These etiquettes of avoidance furnish an indication of the direction of change in social habit among mankind: there are eight peoples (for instance, the Zulus) where residence is in the husband's family, with the accompanying avoidances, but at the same time avoidance is kept up between the husband and the wife's family, indicating that at a recent period he may have habitually lived with them. The method of tracing connection between customs was next applied, with the aid of diagrams, to the two great divisions of human society, the matriarchal and the patriarchal, or, as Dr. Tylor preferred to call them, the maternal and paternal systems; and the method showed that the drift of society has been from the maternal to the paternal system. Examination was next made of the practice of wife capture, recorded among about a hundred peoples, as a hostile act, a recognized and condoned mode of marriage, or a mere formality. It appears from the tables that the rules of human conduct are amenable to classification, so as to show by strict numerical treatment their relations to one another. It is only at this point that speculative explanation must begin, guided and limited in its course by lines of fact. In the words of Prof. Bastian, the future of anthropology lies in statistical investigation. Dr. Tylor's paper showed that the institutions of man are as distinctly stratified as the earth on which he lives, succeeding one another independently of difference of race and language, by similar human nature acting through necessarily changing conditions of savage, barbaric, and civilized life.

Royal Meteorological Society, November 21.—Dr. W. Marcet, F.R.S., President, in the chair.—The following papers were read:—Results of an investigation of the phenomena of English thunderstorms during the years 1857–59, by Mr. G. J. Symons, F.R.S. This paper was written nearly thirty years ago; it has now been communicated to the Society at the request of the Thunderstorm Committee. The paper contains a summary, chiefly in statistical form, of some of the results of an investigation into English thunderstorms and the accidents produced by lightning during the years 1857–59. The author found that in sheet-lightning the most prevalent colour is white, then yellow, blue, and red. In forked lightning the order is nearly reversed, blue being more than twice as frequent as any other colour, then red, white, and most rarely yellow. Sheet-lightning was seen about twice as often as forked.—Notes on the meeting of the International Meteorological Commitee at Zurich in September 1888, by Mr. R. H. Scott, F.R.S. The Committee recommended certain rules for the publication of data by travellers, &c., so as to insure their being useful for the advancement of sound climatological knowledge. The proposals for an international cloud nomenclature, as recommended by Mr. Abercromby and Prof. Hildebrandsson, did not commend themselves to the Committee, who suggested that the subject should be further studied. At the conclusion of the meeting the Committee was dissolved.—On a method of photographing cirrus clouds, by Dr. A. Riggenbach. The author exhibited some photographs of cirrus and other fine clouds which had been obtained by using the surface of the lake as a polarizing mirror.—Mr. A. C. Stratten exhibited some models of very large hailstones—spheres about $2\frac{1}{2}$ inches in diameter—which fell at Montereau, about forty miles south-east of Paris, on August 15, 1888.

Geological Society, November 21.—W. T. Blanford, F.R.S., President, in the chair.—W. Whitaker, F.R.S., who exhibited a series of specimens from the deep boring at Streatham, made some remarks upon the results obtained.—The following communications were read:—Notes on the remains and affinities of five genera of Mesozoic reptiles, by R. Lydekker. This paper was divided into five sections. In the first the author described the dorsal vertebra of a small Dinosaur from the Cambridge Greensand, which he regarded as probably identical with the *Syngonosaurus*, Seeley. The second section described an axis vertebra from the Wealden of the Isle of Wight, which is evidently Dinosaurian, and may possibly belong to *Megalosaurus*. In the third section the femur of a small Iguanodont from the Oxford Clay, in the possession of Mr. A. R. Leeds, was described. The imperfect skeleton of a Sauropterygian from the Oxford Clay near Bedford, which formed the subject of a previous communication, was redescribed. The paper concluded with a notice of the affinities of the Crocodilian genus *Geosaurus*.—Notes on the Radiolaria of the London Clay, by W. H. Shrubsole.—Description of a new species of *Clupea* (*C. vectensis*) from Oligocene strata in the Isle of Wight, by E. T. Newton.

PARIS.

Academy of Sciences, November 26.—M. Janssen in the chair.—On the difficulty of obtaining the exact latitude of the Paris Observatory, by M. Mouchez. In connection with M. Faye's recent communication on this subject, the author states that some improved instruments will soon be fitted up in the Observatory with a view to overcoming some of the almost insurmountable difficulties attending the accurate determination of the latitude of this spot. But even so, it is feared that perfect accuracy cannot be expected, the errors of a few tenths of a second being apparently due rather to the irregularity of the astronomic refractions in the Paris atmosphere than to defective instruments and errors of observation.—On the traction of canal and river craft, by M. Maurice Lévy. It is shown that in the present state of science the mechanical method of traction by means of the telodynamic cable is preferable to any electric system. Various improvements are also described, by which the author and his associate, M. Pavie, have succeeded in surmounting the many obstacles hitherto attending the successful application of the telodynamic cable to inland navigation.—Fresh experiments on the quantitative analysis of the nitrogen present in vegetable soils, by MM. Berthelot and G. André. The researches here described have been carried out for the purpose of testing the accuracy of the analyses hitherto made by various practised chemists operating at different intervals of time and under diverse conditions. Incidentally an attempt has also been made to determine the degree of stability possessed by the nitrogen present in different soils and exposed to varying influences.—On the results of the fourth scientific expedition of the *Hirondelle*, by Prince Albert of Monaco. This expedition, like the previous, was mainly confined to the Azore waters, which were explored in all directions during the summer of the present year. Amongst the improved appliances were two detachable bagging nets with 4000 metres of steel wire, a submarine electric lamp of the newest type, a Thibaudier sounding apparatus with 8000 metres of steel wire, special boats and camping fittings for the exploration of inland waters. Besides rich marine captures in depths ranging from 20 or 30 to 2200 metres, fourteen lakelets were visited, of which thirteen had never been explored and five not yet figured on any maps.—On the application of electrolysis to the treatment of tumours, by M. Darin. Since the recent foundation of the Henry Giffard Clinical Establishment in Paris, the author has effected several remarkable cures by this process. The apparatus is of a very simple character, easily controlled, and fitted with the chloride of zinc pile of the Gaiffe system.—On the determination of the coefficients of expansion at high temperatures, by M. H. le Chatelier. A new process is described, by means of which the author hopes to overcome the great difficulty attending the exact determination of these coefficients, which, apart from their scientific interest, are of such great importance for industrial purposes. The results of some preliminary experiments are given for Bayeux porcelain, iron, steel, and nickel at temperatures ranging from 20° to 970° C.—On an astatic electrometer, by MM. R. Blondlot and P. Curie. The instrument here described is a modification of Sir W. Thomson's electrometer with quadrants, and amongst the various uses to which it is applicable is that of a wattmeter.—Influence of water-surfaces on atmospheric polarization, and observation of two neutral points right and left of the sun, by M. J. L. Soret. Marine and lacustrine surfaces are shown to produce important perturbations on the phenomena of atmospheric polarization. Under certain conditions the curious phenomenon is also observed of two neutral points at the altitude, and to the right and left, of the sun. The polarization is then in a vertical plane between these points, and in the opposite direction beyond them.—On a new process of disinfecting the hands after surgical operations, by MM. Jules Roux and H. Reynès. The process in question is that recently introduced by M. Furbringer; but the experiments here carried out for the purpose of testing its efficacy have given unsatisfactory results in the case of microbes deposited under the finger-nails.—M. Charles Brongniart communicates a paper on Entomophthoræ and their application to the destruction of noxious insects; and M. Marcel Bertrand has a note on a new problem in the geology of the south of France, suggested by the appearance of certain Triassic marls cropping out above the Cretaceous rocks in the neighbourhood of Marseilles.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

THE ZOOLOGICAL RESULTS OF THE "CHALLENGER" EXPEDITION.

Report on the Scientific Results of the Voyage of H.M.S. "Challenger" during the Years 1873–76, *under the command of Captain George S. Nares, R.N., F.R.S., and the late Captain Frank T. Thomson, R.N.* Prepared under the superintendence of the late Sir C. Wyville Thomson, Knt., F.R.S., &c., Director of the Civilian Staff on board, and now of John Murray, LL.D., Ph.D., &c., one of the Naturalists of the Expedition. Zoology—Vol. XXVII. Published by Order of Her Majesty's Government. (London: Printed for Her Majesty's Stationery Office, and sold by Eyre and Spottiswoode, 1888.)

THE first Report in this volume is by Prof. J. R. Henderson, M.B., on the Anomura. Some time after the return of the *Challenger*, the collection of Anomura was placed in the hands of Dr. Jules Barrois; but, not finding time sufficient for their investigation, Dr. Barrois was compelled to return them, and they were placed in Dr. Henderson's care towards the end of 1884.

This group of Crustacea, taken in the sense of Dana, is intermediate between the Brachyura and the Macrura, but in the classification adopted in this Report the author has, to a certain extent, followed the arrangement of Boas, though retaining the Dromidea and Ranidea within the limits of the group—this latter not without some hesitation.

The Anomura are found in all seas, but much more abundantly in those of tropical or temperate climates; some few forms are terrestrial or fluviatile. The greater number inhabit shallow water or moderate depths; two groups, however, the Pagurids and the Galatheids, are numerously represented in the great ocean depths. The collection contained 161 species or well-marked varieties, referable to fifty-two genera, and of these, over one-half of the species (eighty-six) and seven of the genera are described as new. While some of the common shallow-water forms are absent from the collection, still it adds very considerably to our knowledge of the distribution even of this section.

The main interest, however, is in the deep-sea forms, and these chiefly belong to the Paguridea and the Galatheidea, more than four-fifths of the species taken belonging to these groups, and the latter contains the greater proportion of the species.

While the structural modifications met with in the deep-sea species of the Paguridea are comparatively few and unimportant, in the species of Galatheidea the abyssal forms are blind, and the eyes have undergone a process of degeneration which is tolerably uniform in all. In the majority of the species—with the exception of those belonging to the genus Munida—the eggs carried by the females were found to be few in number and of remarkably large size, leading to the inference that their enemies were but few. No facts in reference to their coloration were observed, as the strong alcohol in which the specimens were preserved reduced them all to a dull white colour. Thirty-one plates accompany this Report.

The second Report is by Prof. P. Pelseneer, on the anatomy of the deep-sea Mollusca. The material for this Report could not be placed in Dr. Pelseneer's hands until the systematic Report on the species had been completed, and it consisted exclusively of Gastropoda (not including Isopleura or Amphineura) of Scaphoda, and of Pelecypoda; there was no great wealth of either species or of specimens. Of certain forms there were but single specimens, and in the case of others the soft parts had been injured in removing them from the shells; still, many new and very interesting facts have been noted and recorded, the chief conclusions from which, so far as the special sense-organs are concerned, are as follows. The organ of vision may atrophy and disappear, in consequence of the absence of sufficient light, in great depths; correlatively, the organs of general sense may multiply, and acquire a high degree of development, such as the labial palps of *Trochus infundibulum*, the siphonal tentacles of varied structure in the deep-sea Anatinacea and in Malletia; and, lastly, the respiratory activity may diminish, and the gills become rudimentary in various ways, or these may retain a great simplicity of structure. Four plates accompany this memoir.

The third Report is by Prof. W. C. McIntosh, F.R.S., on *Phoronis buskii*, n. sp. The genus Phoronis was established in 1856, by Dr. Strethill Wright, for a minute Polyzoan, about 1½ millimetre in length. Since this species (*P. hippocrepia*, St. Wright) was described, other species, also of more or less small size, have been described by various authors, from the coasts of Scotland, the Mediterranean, and Eastern America. One, from Australia, is of considerable length. The species dredged by the *Challenger* in shallow water at depths varying from 10 to 20 fathoms (Station 212) south of the Philippine Islands, measures 52 millimetres in length, with an average diameter of about 2 millimetres at the anterior region, and of 4 to 5 millimetres at the enlarged posterior end. The tentacular or branchial region is from 6 to 7 millimetres in length. There has always been a great deal of interest taken in the species of this genus, owing to their strange metamorphosis, and to the uncertainty that seemed to attach to their position in the animal kingdom; this now is settled to be in Ray Lankester's section "Vermiformia," of the Polyzoa. In this Report the minute structure of the *Challenger* species, called after the late George Busk, is given in detail, and figured on four plates. The history of the development of this fine species remains to be written.

The fourth Report is by Prof. W. A. Herdman, on the Tunicata. The first part of this Report, published in 1882, treated of the Simple Ascidians, while the second part, published in 1886, was occupied mainly with an account of the Compound Ascidians, with a supplementary account of some Simple Ascidians which had been found after the publication of the first part. The present part treats of the "free-swimming" Ascidians, which, however, fall into three very distinct groups, less allied to one another than the Simple Ascidia are to the Compound Ascidia. One of these is the group of Salpiform Ascidia; the other two are the Thaliacea, including

such genera as Doliolum and Salpa, and the Larvacea, containing the Appendicularia.

By far the greater number of the pelagic Tunicata collected during the voyage of the *Challenger* belonged to the genus Salpa. Of these, vast numbers were taken at the various stations, so that a great deal of labour was spent in a critical examination of these before it could be determined that they were all the same or different species.

The collection of pelagic Tunicata contained about twenty-six species, of which nine are new to science. No new genera are established, but a new family, the Octacnemidæ, has been formed for the reception of the remarkable deep-sea genus described by Moseley as Octacnemus.

Prof. Herdman gives in some detail, at the close of his account of the species and of their geographical and bathymetrical distribution, the conclusions at which, after a prolonged study of this group, he has arrived, as to their relationship and phylogeny; this is accompanied by a graphic representation of the phylogeny of the Tunicata. This important Report is illustrated by eleven plates.

THE BRITISH FARMER AND HIS COMPETITORS.

The British Farmer and his Competitors. By W. E. Bear. (London: Cassell and Co., Limited, 1888.)

THIS small volume of 160 pages is in some respects a reprint of articles published in the *Quarterly Review*, revised and brought down to date. The first chapter is devoted to the condition of British agriculture, in which the somewhat Radical doctrines of the Farmers' Alliance (an organization which has never succeeded in winning the confidence of the farmers) are promulgated. "Before this country will be cultivated to the best advantage, those who cultivate it must be either the owners of their farms, or tenants who are entitled to sell their improvements to the highest bidder, and who are free to crop the land as they please, provided that they be liable for actual damage done to the property of the owner." "Our farmers must have complete security for their capital invested in improvements, and freedom of enterprise as well, if they are to do the best they can with the land." This is the panacea for agricultural distress, and yet we may well ask why it is that Britain is exceptionally well cultivated, and that farmers as a rule farm as well or better than landlords? Landlord farming has, in fact, for the most part not been satisfactory, either when carried out on the large or on the small scale, and whether any advantage would accrue from its extension is exceedingly doubtful. Allotments, too, are put forward as amongst the requirements of our time, and small farming is also advocated, although condemned by experience.

Mr. Bear is more happy as a statistician than as a politician, and his chapters upon foreign competition and the prospects of the wheat-grower, and the breeder and feeder of live stock, are deeply interesting. The first welcome truth is that in almost all articles of agricultural production the crisis of injurious foreign competition appears to have been passed about the year 1883 or earlier. Such was the case up to date, with regard to wheat, barley, oats, and cattle. The maximum importation of sheep, hops, and potatoes, took place in 1882; of bacon, hams, and preserved meats in 1880; of pigs and cheese in 1878; and of beans in 1877. It must be understood that quantities in quarters and hundredweights, and not values, are indicated; and so considerable has been the shrinkage that the present imports of meat fall short of the maximum reached some eight years ago by about one million hundredweights, chiefly bacon.

Taken in connection with this diminution of foreign supplies of grain and meat, is to be noted the increase in population, not only at home and in Europe, but throughout our colonies and in the United States. In the last-named country alone, population has increased from 38,500,000 in 1870 to 62,500,000 at the beginning of the present year, and it is estimated that it will have reached 66,000,000 by 1890. During the five years ending with 1884 the average annual consumption of wheat in the United States was nearly 324,000,000 bushels, and the average export was 140,000,000 bushels. If the production in the five years ending with 1894 does not become greater, all but 43,000,000 bushels, or less than 5,500,000 quarters, will be required for home consumption, and the surplus will not suffice for the increased population of the next five years. Thus, unless the area of wheat-growing is greatly extended, the United States must cease to be a wheat-exporting country before the close of the present century! There is certainly a somewhat large "if" to swallow in accepting this statement, but it seems pretty evident that wheat-growing is not profitable at present prices, and that American farmers are becoming tired of it. Higher prices can alone cause the necessary increased supply, and the influence of such higher prices would be found in Europe to the advantage of the farmers. Considerable space is devoted to show that American and Canadian farmers grow wheat at a direct loss. It appears that the average gross money return from an acre of wheat in the United States is £1 13*s*. This figure is based on official information, and is arrived at by a yield of 12·2 bushels per acre, and a price of 68·1 cents. the bushel. As, however, the farmers have been often obliged to sell at 48 cents. per bushel, and the yield is in one State, not 12·2 but, 5 bushels, and in another 7 bushels, and in eight States it is below 8 bushels, the gross value of an acre of wheat must in many cases fall much below the average. It is held that unless 20 to 25 bushels can be secured no profit is possible. The cost of growing an acre of wheat in the States cannot, it appears, be placed under 14·11 dollars per acre, *i.e.* about or near £2 18*s*.; and if these figures are even approximately correct, the wheat-growers of the Far West must be in a worse plight than our own. Although nominally rent free, the Western farmers have generally been obliged to mortgage their farms at an interest of from 8 to 10 per cent. per annum, and according to one authority, "teams, tools, stock, and grain, all are being rapidly mortgaged." It is generally admitted that the American farmer's life as a rule is one of "excessive and almost incessant toil, and the scantiest reward—in money, at any rate; while his wife is held up in America as a common object of pity." With such encouragement, Mr. Bear does not expect wheat-growing to spread in America unless prices generally rise.

The second part of the book is devoted to our meat supply and dairy produce. The greatest scare among home meat-producers has been occasioned by the increasing imports of frozen meat—chiefly mutton. The future of this trade is, however, very dubious, and exportation completely collapsed when prices fell in 1886 and 1887. A New Zealand colonist, writing to the *Otago Witness*, says:—"The producer, when he sends his meat to London, realizes about 4½*d*., perhaps only 4*d*., per pound; and when he deducts expenses, say 2½*d*., he has only about 1½*d*. per pound for the choice of his flock. Now, this will not pay him, and some of our largest exporters of meat have decided that it will not pay them to send home their meat."

Mr. Bear's views on the future of English farming are, on the whole, hopeful, but he is accused by some of his critics of being an optimist. He has also brought down the wrath of the Canadian Press upon him for decrying the climate of Manitoba as a wheat-growing area, and discounting the reports of its fertility. As published under the auspices of the Cobden Club, the bias of the work is in favour of free trade, if we may except the trade in live stock, where contagious diseases are involved. Some political or economical bias ought to be accepted as inseparable from a book so issued. The reader will no doubt exercise judicious discrimination in accepting all the deductions, but will not fail to see that Mr. Bear's arguments are well supported by facts and official figures. The book is, in fact, a valuable contribution towards the solution of a question of vast importance—the future of our agriculture.

COLEOPTERA.

Biologia Centrali-Americana—Zoology: Coleoptera. Vol. I. Part II. By David Sharp, M.B., F.Z.S., &c. (London: R. H. Porter, 1882–87.)

ALTHOUGH nearly six years have been required for the completion of this volume, entomology has received a valuable contribution, which is at the same time an evidence of the untiring industry of its author and of the great liberality and enterprise of its editors. The volume covers about 840 pages, illustrated by nineteen plates, including in its scope nine divisions of the Coleoptera, called families, as follows: Haliplidæ, Dytiscidæ, Gyrinidæ, Hydrophilidæ, Heteroceridæ, Cyathoceridæ, Parnidæ, Georissidæ, and Staphylinidæ, in dealing with three of which Dr. Sharp had already shown a rare combination of analytical power and synthetic skill.

While the arrangement of the families in the order indicated above might be criticized as somewhat unnatural, it is to be presumed that the convenient division of labour among the different authors, and the approximation of the labours of each in one volume, had more to do with the sequence than the desire to indicate affinities.

The family *Haliplidæ* presents no point worthy of special mention; there are three new species in a total of six.

The *Dytiscidæ* is represented by 168 species, of which about seventy-one are new, nearly all small species, while the thorough analytical study previously given to the family by Dr. Sharp has left but one generic division to be indicated.

The *Gyrinidæ*, represented by twenty species, of which four are new, presents nothing of note, except the evident tendency of Gyretes to replace Gyrinus in the warmer parts of America.

The *Hydrophilidæ* contains 141 species, four-fifths of them new, requiring the indication of thirteen new genera. In the study of this family, Dr. Sharp gives evidence of the close attention he has devoted to it from the commencement of his career as an author, and he has shown how much new work may be done even in those families moderately well studied. The point seems well taken that the Hydrophilidæ constitute a family, and not a complex equivalent to the Adephaga. While no new arrangement of the family is proposed, the inaccuracy of our present method is shown, and numerous structural differences are indicated, which may form the basis of a better system when more is known of the genera from other regions than Europe and North America.

The next four families, Heteroceridæ, Parnidæ, Georissidæ, and Cyathoceridæ are all of small extent, containing between them but fifty species. While these are closely related among themselves, their position in mass between the Hydrophilidæ and Staphylinidæ is unnatural, and obscures their evident relationship with the Byrrhidæ and certain Dascyllidæ.

The greater portion of the volume is occupied with the treatment of the Staphylinidæ, in which more than 1400 species are enumerated, seven-eighths of them new; of the remaining eighth a fair proportion had already been described by Dr. Sharp elsewhere. The mere numerical statement will give but an inadequate idea of the labour expended in this part of the volume. Those who have had occasion to deal with the Aleocharinæ will realize the amount of minute examination required, almost ruinous in its effects on the eyesight. It is evident that the Staphylinide fauna of Mexico is far from being exhausted, and had as enthusiastic collectors as Mr. G. C. Champion collected in other parts as he did in his regions, it is safe to believe that the number of species would have been more than doubled. In a notice like the present it seems unnecessary to enter more deeply into details. Although much has been done in Staphylinidæ, our knowledge of the fauna of Europe is the only one approximately complete, and it gives a very narrow basis for comparison.

As a whole, Dr. Sharp's work will receive the recognition due to careful, conscientious, and erudite labour. It is to be regretted that the descriptions are at times too brief; and how much difficulty future students may find in following them may be inferred from the experience of Dr. Sharp with the longer and very able descriptions of Erichson.

The volume concludes with nineteen plates, with about 450 figures, which will prove useful in the identification of the species. The omission of details is to be regretted, although their representation would have given Dr. Sharp an amount of labour which he could hardly be expected to undertake.

G. H. H.

OUR BOOK SHELF.

A Sequel to the First Six Books of the Elements of Euclid. Fifth Edition. By J. Casey, F.R.S. (Dublin: Hodges, 1888.)

THIS handy book has been a decided hit, and has supplied something that was really needed. The main body of the work is little altered in the present edition, but corrections have been made of slips which we had occasion to point out. The special part, *i.e.* the supplementary chapter on the recent elementary geometry, continues to grow. In the last edition, pp. 165–222 were devoted to it; in this, pp. 165–248. Additional articles are devoted to Taylor's circle (Mr. Taylor's paper in the *Messenger of Mathematics*, vol. xi., appeared before his article in the Mathematical Society's Proceedings, vol. xv., and some of the properties of it were given in a Trinity College, Cambridge, examination paper (*l.c.*); see, however, Simmons, "Recent Geometry," in "Milne's Companion," p. 181). Much of Section vi., on "The Theory of Harmonic Polygons," has been rewritten, and indebtedness to Messrs. Neuberg and Simmons is admitted. The impression conveyed to a reader is that the latter's important article, referred to above, has not been seen by Dr. Casey, for, if it had been seen by him, frequent reference must, we should suppose, have been made to it, whereas the only reference is to a note in the Mathematical Society's Proceedings, April 1887. We now commend the article in question to Dr. Casey's notice. Section vii., on the "General Theory of Associated Figures," is for the most part new to the volume,[1] and there are additional exercises. We would point out that Questions 76, 77 (p. 217, fourth edition, and p. 241, fifth edition) are not consistent. 76 is right; in 77 read, for "*orthocentre* of pedal triangle," "symmedian point," as in the author's "Conics," p. 325.

Elementary Theory of the Tides. By T. K. Abbot, B.D. (London: Longmans, Green, and Co., 1888.)

FULL discussions of tidal action and its effects have hitherto been confined to treatises which employ higher mathematics, and any successful attempt to simplify matters ought therefore to receive a hearty welcome. The book before us is an attempt at this, and although it only consists of some forty pages, it simplifies many points. The proofs of the various theorems require no special knowledge beyond that of the resolution of forces, but the quantitative determinations necessarily demand a little mathematical knowledge.

There is a common notion that without friction there would be high water under the moon, but Mr. Abbot easily demonstrates that it would occur at quadratures. A simple construction is given and proved for the determination of the amount of the disturbance at any point on the equator. The influence of tides upon the length of the day is also discussed. Airy's analytical method is given in an appendix.

The book is mainly a compilation of papers by the author which were published in 1871-82 in the *Philosophical Magazine* and other journals.

Pictures of Native Life in Distant Lands. Depicted by H. Leutemann. With Explanatory Text by Prof. A. Kirchoff; translated from the German by George Philip, Jun. (London: George Philip and Son, 1888.)

TWELVE coloured plates, illustrating what are called the typical races of mankind, are brought together in this volume. The subjects have been well selected, and the workmanship of the pictures is sufficiently good for the artist's purpose. The letterpress, by Prof. Kirchoff, contains much valuable information, and it has been translated by Mr Philip into clear and simple English. The work will both amuse and instruct any young readers who may be fortunate enough to obtain a copy.

[1] M. Torry's paper reached the author as his fourth edition was in the press, see pp. 221, 222 of that edition.

The Zoo. By the Rev. J. G. Wood. (London: Society for Promoting Christian Knowledge, 1888.)

MR. WOOD is so well known as an expounder of the facts of natural history that it is unnecessary to say much about the present volume. His object is to interest children in some of the animals which they may see in the course of a visit to the Zoological Gardens. He begins with an account of monkeys, and then goes on to talk about lions, tigers, leopards, the chetah, the jaguar, the lynx, wolves, foxes, hyænas, the Aard wolf, bears, and the racoon. In each section he contrives to say something that is worth remembering, and perhaps a good many of his descriptions will be at least as interesting to older readers as to the young people for whom they are primarily intended. The book is prettily illustrated.

Alpine Winter in its Medical Aspects. By A. Tucker Wise. Fourth Edition. (London: J. and A. Churchill, 1888.)

THE present edition of this work contains all the subject-matter of previous publications of the Alpine climate series, with extracts from Dr. Wise's papers read at the Harveian Society of London, the Royal Meteorological Society, and the International Medical Congress held at Washington in September 1887. The writer knows his subject thoroughly, and he has too ardent a belief in the treatment of chest disease in the mountains to wish to make extravagant statements about it. In his representations of Alpine climate he has not forgotten to include those unpleasant details which are generally somewhat vaguely described as "drawbacks." The work contains a series of careful notes on Davos Platz, Wiesen, St. Moritz, and the Maloja.

Animal Physiology. By William S. Furneaux. (London: Longmans, Green, and Co., 1888.)

IF the necessity be granted that a separate text-book should be published to meet the requirements of every examination body in each department of learning, Mr. Furneaux may be said to have met his share of that necessity, and with more success than many of those who have recently set to themselves a similar task. The book covers a slightly wider field than that indicated by the "Elementary" Syllabus of the Science and Art Department for human anatomy and physiology; it is clear and well arranged, and the illustrations are good and carefully selected. Such loose statements as that "bone is produced by the gradual hardening of cartilage" (p. 34) appear to be almost a necessity in works of this stamp, but with Mr. Furneaux they are unusually rare. The volume forms one of Messrs. Longmans' series of "Elementary Science Manuals."

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Hailstones.

A SEVERE hailstorm occurred here yesterday evening, between 6 and 7 o'clock, and lasted for about a quarter of an hour. The hailstones being fairly large, I was able, by the aid of a good lens, to examine them somewhat carefully. The result of this examination I give shortly in the following statement.

All the hailstones were pyramidal in form, and the pyramids were nearly all four-sided. Their bases were in almost every instance more or less rectangular in outline, the contours of a few only being triangular, and the surface of each base was convexly curved. The general length from the centre of the base to the apex was about a quarter of an inch; the longer diameter

of the base was nearly three-sixteenths of an inch, while the shorter basal diameter was about a sixteenth less. Of course, the above measurements are merely general, and were necessarily taken in a rather rough fashion.

The figures 1, 2, 3 below, although diagrammatic, will give a better idea of the usual shape of the hailstones than could be readily furnished by any further detailed description.

When sixteen hailstones, all of which were practically of the same size, were placed closely together side by side, so that all their apices terminated at the same point, a half spheroid was constructed, the curved basal surfaces of the pellets running neatly into one another to form the external globular surface. It

Fig. 1.—Magnified.

Fig. 2.—Magnified.

Fig. 3.—Basal view; magnified.

is evident, therefore, that those particular hailstones, at least, were originally portions of spheroids, each hailstone being a segment (the 1/32nd in this case) of a globe. How the icy globes were formed, and what was the cause of their breaking up into segments, are problems, I believe, that yet await serious investigation.

When the substance of any of the hailstones was observed closely by means of a lens magnifying four times, it was seen to be a transparent mass of ice, and fairly homogeneous in texture, having apparently little or none of the fibrous structure which has been previously noticed in other cases, and recorded by myself and other observers (see NATURE, vol. xxxv. pp. 413, 438,

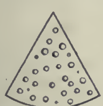

Fig. 4.—Showing numerous liquid cavities in a hailstone; magnified six times.

536). Each icy mass, however, contained scattered about in its substance numerous small cavities, round, oval, or elliptical in form, which were filled wholly or partially with water (see Fig. 4).

In some cases these liquid cavities were so numerous and so crowded together as to interfere seriously with the diaphaneity of the hailstone and to give it quite a clouded or granulated appearance. I may add that the convex basal surfaces of the hailstones were not quite smooth and glassy, but exhibited a rather grainy appearance, and were slightly but distinctly rough to the feel.

ALEXANDER JOHNSTONE.

Edinburgh University, November 29.

The Renaissance of British Mineralogy.

THE following passage occurs on p. 116 of NATURE of November 29, in an article on the above subject :—

"Crystallography should be taught as a special subject; and a knowledge of it should be required not only of the mineralogist but of the chemist, and even of the physicist. Hitherto, at least, the chemists of this country have been too content either to leave the crystalline forms of their artificial products undetermined, or to impose the task of their determination on the already sufficiently occupied mineralogist. It seems obvious, that in a satisfactory system of education every chemist should be taught how to measure and describe the crystalline characters of the products which it is his fate to call into existence. On various occasions expression has been given to this view, but the only chemist who has yet seen his way to act upon it is Prof. Henry Armstrong, who I am happy to say, has introduced the subject into the educational course of the City and Guilds Technical Institute. I trust that before another generation passes away his excellent example will be followed throughout the country. A knowledge of the elements of crystallography, including the mechanics of crystal measurement, ought to be made a *sine quâ non* for a degree in chemistry at every University."

The views thus expressed are shared by many chemists, and are, I believe, generally known. It is, however, not exactly correct that "the only chemist who has seen his way to act upon it is Prof. Henry Armstrong."

Long before the City and Guilds Institute was established or thought of, mineralogy, including crystallography, was a part of the curriculum in the Department of Engineering and Applied Science in King's College, London.

Until the year 1879, mineralogy and crystallography were studied in the Royal College of Science, Dublin, by students in the Faculty of Mining only, but at my suggestion these subjects were made compulsory on the students in all Faculties.

Furthermore, this subject was introduced into the course pursued in this College by the candidates for the Associateship of the Institute of Chemistry, the Council of the Institute accepting attendance at the course of mineralogy as equivalent to an equal number of hours in the chemical laboratory. This arrangement was carried out in 1881. It will be seen that mineralogy and crystallography are subjects which have by no means been neglected by chemists, though it is quite true that, like many other science subjects, they have not taken their proper places at the Universities. To chemists generally, there are without doubt more important subjects of study than crystallography which are not adequately taught; I refer to the use of the microscope, polarimeter, and spectroscope. These instruments are employed, and are absolutely indispensable, in certain methods of chemical analysis and research.

In how few laboratories are any accurate measurements of spectra made, or is the spectroscope used for any other observations than for detecting the alkalies and alkaline earths!

We have as yet no Professor of Spectrum Analysis, though it is undoubtedly a fit subject for a distinct Professorship, and this fact has, I believe, been recognized in Germany. If the advances in chemistry made respectively by students of crystallography and of spectroscopy be compared, it will appear that we owe very much more to the latter than to the former.

W. N. HARTLEY.

Royal College of Science, Dublin, December 1.

"Weather Charts and Storm Warnings."

I HAVE just been reading Mr. Allan Broun's review of Mr. Robert H. Scott's "Weather Charts and Storm Warnings," in NATURE, vol. xiv. p. 566, and note that the reviewer says :—

"Why, in all the disquisitions on fluid equilibrium, are the constant low (barometric) pressures in the Antarctic regions south of 60° neglected? How shall we account for the permanent depression in the neighbourhood of Iceland referred to by the author (p. 64)? And, to come to our own country, how will cyclonic winds explain the fact that the pressure of the atmosphere diminishes, on the average of the whole year, at the rate of one-tenth of an inch of mercury for 4° of latitude as we proceed northwards?"

I have no suggestion to offer respecting the depression near Iceland, but the other two—the depression about the South Pole, and the diminution of pressure going northwards in Great Britain—are parts of one general fact—namely, the diminution of pressure in going from about lat. 30° to either Pole, which, however, is most marked in the southern hemisphere. This, I think, admits of a simple explanation. The zones on each side of the equator are occupied by the trade-winds, blowing from the east: their cause is too well known to need statement here. But, by the law of reaction, they necessitate the existence of winds of equal total force from the west, and those west winds are formed in the regions between the trade-winds and the Poles. Winds blowing continuously round the Poles, in the same direction as the earth's rotation, constitute vortexes, and the pressure at the bottom of the vortex—that is to say, at the earth's surface—necessarily diminishes towards the centre—that is to say, towards each Pole. The diminution of pressure towards the Pole is much greater in the southern than in the northern hemisphere, because in the latter the unequal heating of continents and oceans produces currents of wind which, though on a large scale, are local currents in respect to the entire hemisphere, and tend to break up the vortex.

The cause I have assigned is a *vera causa*—that is to say, it is known to exist, and its effect must be of the nature of the effect actually found. Perhaps some of your mathematical correspondents will discuss the question whether it is of sufficient magnitude to account for the effect.

Belfast, December 2. JOSEPH JOHN MURPHY.

The Philippine "Tamarao."

In 1878 I reported in a letter to Dr. Sclater, the existence of a species of *Anoa* in the Island of Mindoro, on the strength of an example of the *Tamarao* labelled *Anoa depressicornis* in a Museum at Manilla. Having since seen living specimens of the Celebean *Anoa*, I have no hesitation in affirming that the latter animal has not even a superficial resemblance to the *Tamarao* which I saw at Manilla. I have now no doubt that the *Tamarao* of the Manilla Museum is a buffalo,—not, however, an immature example of the common buffalo, as has been suggested, but a distinct species, with short flattened horns sloping directly backwards.

A. H. EVERETT.

41 York Terrace, Regent's Park.

A Pheasant attacking a Gamekeeper.

As the keeper was walking home, a distance of half a mile, through the plantations near his cottage, a pheasant flew at him three times, attacking his legs in a most savage manner. The keeper got to his cottage with the pheasant after him, and called his wife out to witness the incident.

The keeper was able to secure the pheasant and return it to the cover. I should be glad to know if such conduct is exceptional on the part of game birds.

Walk House, Barrow, Hull, November 30.

THE MORPHOLOGY OF BIRDS.[1]

I.

THIS magnificent work, consisting of two folio volumes, with more than 1700 pages of closely printed text, and illustrated by more than thirty artistically executed plates, is the latest of the "Bijdragen tot de Dierkunde" ("Contributions to the Knowledge of Animals"), published by the Royal Zoological Society, *Natura Artis Magistra*, of Amsterdam, on its fiftieth anniversary. It is the parting gift to that Society of its grateful author, who, one of Prof. Gegenbaur's ablest pupils, now fills the Chair of Anatomy in the University of Jena; and it is needless to say that the publication of so monumental a work reflects the highest credit upon the Society of Amsterdam. It is monumental not merely from its bulk, but chiefly from the enormous amount of information it contains, much of it bearing upon some of the most deeply-rooted questions of importance to the general morphologist, and above all on the natural affinities—that is to say, the phylogeny—of birds both living and extinct.

In what follows I make no attempt at a critical review, but give as complete a summary as possible of Prof. Fuerbringer's work, which I trust will be acceptable to English readers, for few of them will have the opportunity of seeing these costly and weighty volumes, or the perseverance to master their contents, and yet it cannot be but that many would like to know the results at which the author's investigations have led him to arrive.

The whole work consists of two parts.

The special part comprises the first 837 pages, and is devoted to a minute and most comprehensive description of the bones, nerves, and muscles of the avian shoulder-girdle in the widest sense. The investigations extend over many hundreds of birds of all orders and families; frequently numerous specimens of the same species have been examined in order to ascertain the extent of individual variability.

The author justly asks himself if it is not too much to offer such a bewildering mass of mere detail to the public; but he considers it indispensable that the reader, who may not easily yield acceptance to the generalizations, should be offered the fullest opportunity to re-examine the facts in detail, and to follow step by step the road which has led the author to his conclusions.

[1] "Untersuchungen zur Morphologie und Systematik der Voegel, zugleich ein Beitrag zur Anatomie der Stuetz- und Bewegungsorgane." Von Max Fuerbringer, Professor der Anatomie, und Direktor des anatomischen Instituts und des Museum Vrolik der Universitaet zu Amsterdam. Mit 30 Tafeln. (Amsterdam: T. van Holkema, 1888.)

At the same time, it must be borne in mind that the first part of the work is not merely descriptive, but that it contains a series of complete essays on the morphology of the organs under consideration. The treatment of the structure, development, and modifications of the sternum, for instance, takes up not less than 78 pages. In the myological part particular attention has been bestowed upon the proper naming and homologizing of the muscles.

The descriptive detail deposited in the special part has been used in the *second or generalizing part* as the material for reflections. These lead (*a*) to morphological results, which are important chiefly for the phylogenesis of the skeletal, nervous, and muscular systems; (*b*) they form a basis for a new systematic arrangement of birds. Physiological questions are less dwelt upon, but there are numerous contemplations on the theory of flight, and a remarkable chapter on cold- and warm-bloodedness.

The author remarks that the study of the morphology of birds well repays the labour bestowed upon it, not so much because of the great or fundamental variety which this class of vertebrates exhibits, but rather because several organic systems have reached a height of development which they have not attained in any other class of animals. We often find a richness of organic differentiations within the limits of small groups of birds. It is therefore possible to form a judgment, approaching almost to certainty, as to the primary or secondary significance of these differences. It is interesting to follow the steps which lead to such astonishing heights of specialization.

Pp. 839–996 are devoted to results and reflections of general morphological importance. For instance, the changes in the configuration of the sternum which are brought about by the modifications of the muscles of the pectoral girdle. There is not unfrequently an apparent discord between the passive or skeletal and the active or muscular elements; of these the latter are by far the more progressive, so that the more conservative skeletal parts have not always kept step with the newly introduced changes of the muscles. An example of this is afforded by the wings. By the reduction of the wing, beginning at the distal end, those muscles are first affected which arise from the wing bones, next are affected the bones themselves, and lastly those muscles which are inserted on the same (p. 855).

Syndesmology receives much attention, chiefly by an extensive treatment of the shoulder-joint. Joints are certainly not formed by the action of the muscles during embryonic life, but they are phylogenetically preformed, and only during the post-embryonic stages can the finer configuration of the joints be modelled and influenced by the muscles.

P. 862.—Questions of the greatest importance are involved in the transformation of mere ligamentous connections into symphyses and joints, with the accompanying neoblastic appearance of cartilage. This new cartilage is either homoblastic or heteroblastic. It arises from latent cartilaginous cells, as is the case with the addition of new vertebræ at the end of the Ophidian tail, and probably with the multiplication of the Cetacean phalanges; or the cartilage is due to transformation of periosteal cells, like the patella ulnaris. In such cases the original ligament can be supplanted by bone. On the other hand, the clavicle is sometimes transformed into a ligamentum claviculare.

Fasciæ are often strengthened into aponeuroses and into tendons; they are used as such, not only by their own muscle, but also by neighbouring ones, and this leads to the formation of paratenons or tendinous slips. Birds afford numerous instances in which muscles have gained extra support by "anchoring" themselves to neighbouring fasciæ.

Pp. 877–82 treat of *sesamoid* bodies, of which the author recognizes three sorts. (1) Skeletogenous sesamoids, like the pisiform bone, are, strictly speaking, not

sesamoids, as they are retrograded skeletal parts, which in most cases have been preserved by the surrounding muscles. (2) Arthrogenous sesamoids, like the os humeroscapulare, are derived from the capsule of a joint. (3) Tenontogenous or desmogenous, like the patella, are formed heteroblastically inside of a tendon.

The eighth and ninth chapters (pp. 894–947), form a critical essay on muscles with regard to their connection with the nervous system. After having exhaustively criticized the neuro-muscle theory of Kleinenberg, the various views of Huxley, those of the brothers Hertwig with reference to the cœlom theory, and, lastly, the theory of the secondary connection of muscle- and nerve-fibres as promulgated by Claus and Chun, the author considers the ontogeny, degeneration, and regeneration of muscles and nerves. Lastly, he proceeds to attempt a decision (pp. 920–41).

In connection with this attempt stands a discussion of the inheritance of acquired faculties, and the continuity of germinal and somatic plasma. Fuerbringer believes in Haeckel's law of accumulative adaptation through inheritance. What the individual has acquired during and through its incessant contact with the world can greatly influence its descendants; hence the great importance of the investigation of post-embryonic developmental changes. Throughout the whole book, Fuerbringer, without denying the importance of the ontogenetic features as a recapitulation of the ancestral history, lays more stress upon the study and comparison of the adult forms. In almost every chapter, we come across instances in which the embryonic development does not help to explain certain organs; the recapitulation of their previous stages is too much hurried or condensed, and at the best only that is repeated which had last been acquired.

Fuerbringer accepts Kleinenberg's neuro-muscle theory as the most probable solution. The whole apparatus, which consists of a ganglionic cell, a nervous and a muscular fibre, has been developed from one and the same cell, and is therefore to be looked upon as one organ. The muscle is the end-organ of its nerve, consequently the innervation of the muscles forms the most trustworthy means for the determination of their homologies.

Chapter x. (pp. 947–72) deals with the variability of muscles. Neither the point of the origin, nor that of the insertion, of muscles is a safe guide to their homologies. This shows why muscles are almost valueless for the determination of the homologies of skeletal parts.

Pp. 972–91, on the shifting or migration of the extremities with their girdles along the vertebral axis. This shifting has reached its highest degree in birds. Even individual and one-sided variations are frequent. As a rule, the shifting has been directed backwards, resulting in an increase of the length of the neck. Large birds show a greater amount of shifting than the smaller ones of the same family. A retrograde or secondary shifting towards the head seems to stand in correlation with the degradation of the wings. Hand in hand with the changes of the relative position of the limb and girdle goes a change of the whole thorax. Thoracic vertebræ are turned into cervical, and lumbar into thoracic vertebræ. In most cases, but not always, the number of thoracic ribs remains the same. It looks as if, roughly speaking, the whole trunk with all the organs inclosed in it, did slide along the vertebral axis. The accompanying metamerical transformation of the plexus brachialis is not effected by inter- or excalation of nervous segments, but by the diminution and reduction of one anterior nerve-stem, and the contemporary formation and addition of a nerve nearer to the posterior end of the plexus. The peripheral parts of the plexus retain their configuration in spite of all the changes, and since the only trustworthy safeguard in the homologies of spinal nerves is their number in the series of metameres, two plexuses may be homodynamous, although, strictly speaking, not homologous. This is expressed by the term "imitatory homodynamy," more happily by "parhomology."

The same considerations apply to the muscles. They, together with the nerves, undergo metameric changes until they likewise are only parhomologous. The various muscles of the shoulder-girdle of a bird with thirteen cervical vertebræ may present, in shape, position, and distribution of the nerves, features identical with those of a bird with fifteen cervical vertebræ, but still they are only parhomologous to each other.

This metameric transformation cannot, of course, be watched on those muscles which arise from the shoulder-girdle, but on those which, like the mm. rhomboidales et serrati, arise from the trunk, and are inserted into the girdle. The migration of the whole anterior extremity tailwards necessitates first elongation, then a thinning out, and even total reduction, of those muscles which extended from the neck to the anterior end of the shoulder-girdle. In this way the m. levator scapulæ of the reptiles has become lost by the birds.

Of course the whole problem of the metameric transformation and new formation of muscles and nerves cannot be considered as solved without an explanation of the histological changes which are involved in the question of the parhomology of the muscles together with their nerves. Such an explanation Fuerbringer has not been able to present, but he tries to suggest one by showing how we may imagine those changes to take place.

Most muscles, Fuerbringer argues, are polymetameric, *i.e.* they receive nervous fibres from two or more spinal roots. Moreover, the nerves of the more proximal muscles belong chiefly to the pre-axial or anterior, whilst those of the distal or more peripheral muscles receive their nerves mostly from the post-axial roots of the plexus. The author discards the idea that nerve-fibres can send out buddings into neighbouring new muscles, but thinks that in many cases the formation of new muscles and nerve-fibres is initiated by a splitting. This splitting begins peripherally with the muscle-fibre, is followed by that of the nerve-fibre, and perhaps leads to a division of the ganglionic cell. Ganglionic cells with two axial cylinders of motory nerves are known to occur.

Another possible explanation of the increase of the number of fibres of one nerve and those of one muscle is their derivation from cells which had remained latent in an embryonic or primordial condition between the fully formed muscle- and nerve-cells. Traces of such primordial elements Fuerbringer has found between the fibres of motory nerves, and between the fibres of fully developed muscles; in the latter case they may be identical with the myoblasts of other authors.

Everywhere in nature, in the organism, there is superfluity of material. Tissues and organs seem to be trained by the struggle for existence in such a way that they produce at their beginning an abundance of formative germs and cells, of which under ordinary circumstances only a small part becomes developed into specifically functional tissue-cells. The rest remain in their primitive embryonic condition. They form stored-up plastic material, which may or may not be called upon to meet such extraordinary requirements as may arise from the necessity for the organism to adapt itself to new conditions.

Still greater is the difficulty when the neomorphism (by which word the reviewer has on a previous occasion tried to render into English the meaning of the German term "*Neubildung*,"—new formation not being exactly identical with it) is not confined to the same, but takes place in the next following metamere. For instance, when a muscle, which previously was innervated by the fibres from the 15th and 16th spinal nerves, now receives its supply from the 15th, 16th, and 17th nerves, the explanation given above will be of no avail. The permanent continuity of the two later components of the original neuro-muscle

cells forbids the assumption of a secondary junction; in our case the junction of fibres of the 17th spinal nerve with those fibres of the old muscle which, by migration or by increase in number, have come to be situated on the 17th metamere.

Fuerbringer explains these changes by an ingenious hypothesis, viz. by a peculiar mode of growth, which he terms "growth by metameric opposition or reduction of the muscles and nerves." The primordial extremity was perhaps somewhat broader, and extended over a greater number of metameres. This surplus of locomotory elements was reduced by the following concentration of the limb, but not so completely that those metameres did not in later generations retain *vi inertiæ* the faculty of reproducing some of the nearly lost elements in a primitive condition. The reduction of these germs, that are not called upon, would become complete, they would be lost, but for the particular stimulus which they and their metameres receive from the extremity. The real nature of the interdependence between a stimulus and its effect is still an obscure problem; but we can imagine that the shifting limb exercised a stimulating influence upon the newly overlaid metameres, and that this stimulus awakened the latent nerve-muscle germs, which then joined the already existing apparatus of the approaching limb. Such latent germs, when once started into activity, may well be required to fully develop in order to make up for the reduction of the motory elements at the opposite end of the limb. As a support for this speculation, Fuerbringer alludes to the fact that the anterior limb of birds now tends to shift backwards, and it is the last root of the brachial plexus which contains relatively the greatest number of those immeasurably fine elements that he is inclined to consider as latent germs. The absolutely gradual mode of growth, which this metameric apparition postulates, makes it less perplexing that parts which are only parhomologous should be the very counterfeits of each other.

Pp. 984–91. What has caused the backward shifting of the anterior extremity? To inquire into the causation of the length of the neck means the same problem in a different form. A correlation between the length of the neck and that of the legs is not always there, *e.g.* swans. The assumption of intercalation of vertebræ is still unjustifiable, being quite unsupported by proofs. There remain lengthening of the single vertebræ and the shifting of the extremity along the axis.

In stretching our neck, we bring into play chiefly two sets of muscles, viz. the extensors of the neck and the depressors of the shoulder and anterior limb. There is no reason for assuming that the ancestors of recent birds did not effect the stretching of their necks in the same way. Continued habit results in permanent conditions. In a well-extended neck the vertebræ are in more perfect equilibrium and in conditions more favourable to their nutrition and growth than if the neck were much curved and doubled up. The pectoral girdle, the sternum, and the whole anterior limb of birds are *in toto* retracted by the incessant pulling of the mm. rhomboides, serrati, latissimus dorsi, and the abdominal muscles, the latter so far as they are attached to the sternum. Many of the thoracic muscles show a pronounced tendency to extend their origin tailwards. As a rule, large birds possess more cervical vertebræ than smaller birds, and they are noteworthy for their soaring and more lasting mode of flight. During the time that the wings are not moved, but are kept in a spread-out position, they offer a greater resistance to the air than the far smaller but heavier bulk of the body. The momentum gained by the body will therefore tend to move the latter forwards with more velocity than the resisting wings. In other words, the wings will remain behind the body, and the strain produced by this difference in equilibrium will act upon the ribs, since these form the weakest connection of the sternum + shoulder-girdle + wing with the rest of the body. The anterior thoracic ribs will lose their sterno-costal character, and be transformed into cervical ribs, *i.e.* the neck is lengthened, and the whole pectoral girdle, with the whole apparatus of flight, will be shifted backwards. The reduction of thoracic into cervical ribs can be proved on grounds independent of this question. The long necks of the Ratite birds seem to offer a serious objection to the view just explained, but Fuerbringer pleads in another part of his work (p. 1504) for their being descendants of birds which possessed well-developed power of flight.

Pp. 991–95 contain some remarkable observations about the size of birds. On the whole, small birds show more primitive and simpler conditions of structure, whilst the larger members of the same group exhibit a more one-sided development, and consequently greater deviation from the common stock. The first birds were probably smaller than Archæopteryx. Reptiles and mammals show likewise in their earlier and smaller types more primitive features than do their larger descendants. It is therefore the study of the smaller members within given groups of animals which promises the best results as to their phylogeny.

H. GADOW.

(To be continued.)

STATISTICS OF THE BRITISH ASSOCIATION.

IT may prove instructive to see, in diagram-form, some statistics connected with the history of the British Association. We go back only to 1850 (the Association, it is known, dates from 1831), and our curves relate to the total attendance in each year to the present, to attendance of ladies, and to grants in aid of scientific research.

As regards attendance, it will be seen that the maximum is that of the Manchester meeting in 1887, the figure 3838 having been then reached. Newcastle, in 1863, comes next, with 3335; then Manchester again, in 1861, with 3133. The curve reaches high points also in the case of Liverpool in 1870, Glasgow in 1876, Southport in 1883, &c.

On the other hand, we find the curve reaching its lowest, in this period, at Ipswich, in 1851, with 710; while Hull, in 1853, Swansea in 1880, Cheltenham in 1856, Cambridge in 1862, and Plymouth in 1877, furnish other low points, in rising series.

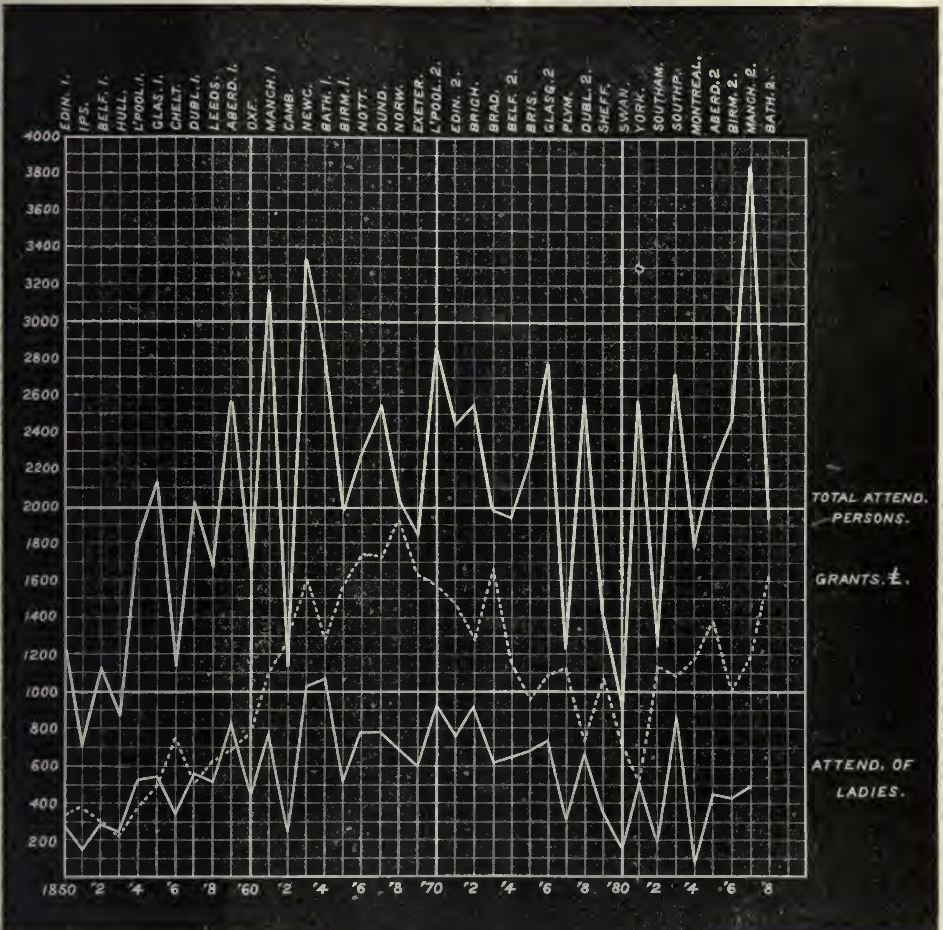
The general course of the curve seems to be that of rise to a maximum at Newcastle in 1863, then descent to Swansea in 1880, followed by another rise to the peak representing Manchester in 1887. The meeting at Montreal (in 1884) it will be seen, takes a fairly good position as to numbers (1777).

Several places had a second visit *in the period considered* (not necessarily second in the whole series); these are indicated by figures after the abbreviated names. How do those repeated visits compare with the earlier? In general, the second visit considerably exceeds the first in numbers. But in the case of Aberdeen the second figure (2203) is less than the first (2564); and the same holds for Bath, 1950 this year, as against 2802 in 1864. The former Bath meeting had no doubt exceptional attractions in the visit of Livingstone, &c. The earlier Aberdeen meeting was presided over by the Prince Consort.

Of the total number, something like one-half are usually associates for the year (paying £1), the others annual or life members, ladies, and foreigners. These groups do not call for special remark here; but we have given a curve of ladies' attendance, as there is room for it, and it is somewhat curious. It seems to have a

slightly downward tendency from the maximum of 1058 at Bath in 1864. Whether this has any significance as revealing change of character in the Association (deterioration or otherwise) we cannot say. Subjects of discussion within the range of average feminine comprehension and interest, have not, we think, been growing in scarcity of late, but rather the reverse.

We might note the much smaller attendance of ladies at Manchester in 1887 (viz. 493) than in 1861 (viz. 791), though the general attendance was much larger in the later year. Again, more ladies attend the meetings in a place like Bath than in one like Newcastle, while the total attendance is greater at the latter: this is only natural. In Brighton, as compared with Liverpool, similarly, there is a larger proportional attendance of ladies. And further discrepancies between the two



curves will be found on examination. The minimum attendance of ladies was at Montreal in 1884, viz. 74.

In the dotted curve showing grants of money for research, we find a rapid rise to a maximum in 1868, when £1940 was paid; then a rapid fall to £476 in 1881; after which the curve mounts again to £1645 this year. In 1872 the grant to Kew Observatory fell from £600 to £300, and the following year it disappears.

A curve of the yearly income corresponds, in the main, with that of the attendance.

The history of an institution, clearly comprehended, should furnish hints as to how the welfare of the latter may best be promoted in the future. Should the teaching of our diagram in this relation be educed through discussion in the columns of NATURE, it may serve a good purpose.

THE MOVEMENTS OF CYCLONIC AREAS.[1]

THE Meteorological Council having undertaken a special discussion of the weather over the North Atlantic and adjacent continents for the thirteen months ending with August 1883, the period agreed upon for the international circumpolar observations, the preparation of the synoptic charts for the same area originally commenced by Captain Hoffmeyer, and since his death carried on conjointly by the Institute at Copenhagen and the Seewarte at Hamburg, was suspended for the time, and a new series was started from September 1, 1883. The charts are issued in quarterly volumes, and the "Vierteljahrs-Wetter-Rundschau" is a carefully-prepared summary of the principal meteorological features in each volume, to which is added a critical examination of the routes followed by sailing-ships from Europe to and from America, and to and from the equator, with tables showing the time occupied by each ship in sailing between certain latitudes and longitudes. Passage tables have always been a favourite study with mariners. Here there are hundreds of voyages tabulated in order of date, so that the sailing qualities of several ships are comparable from being under the same conditions of weather, and the value of the tables is therefore greatly enhanced.

The novel point in the work, however, is the introduction by Dr. Köppen of a new system of discussing the paths of storms. For some years past, meteorologists have been slowly coming round to the opinion that anticyclonic areas exercise a very important influence on the movements of cyclones; indeed, it may be safely asserted that the latter are almost entirely dependent upon the former for every stage of their progress. But although this is daily becoming more manifest, little has been done in the way of improving our mode of tracking cyclones. Ordinary track-charts represent the paths of storms during fixed periods of a calendar month, as if those of the early days were comparable with those of the end of the month—that the tracks, in fact, were regulated by time rather than by changing circumstances. A month's storm-tracks are so numerous, the direction of translation so varied, disturbances travelling in every conceivable direction—north, south, east, and west—and twisting round and round within a small radius, that to trace an individual disturbance is a work of no small difficulty. Even when the tangle is unravelled, there is nothing on the chart to show why one storm travels direct across the Atlantic to Europe in two or three days, another takes ten or eleven days, while others dart off through Davis Strait or by the east coast of Greenland to the Arctic regions; and the consequence is that we are left entirely to theorizing to explain the different movements, and theory has generally sought for the cause within the cyclones themselves. The more we examine synchronous weather-charts the more patent is it that cyclonic areas are strictly limited in their movements, both in rate and direction, by the surrounding conditions.

In NATURE, vol. xxxiii. p. 206, a diagram is given showing the track of a low-pressure system and its influencing anticyclone, the position of the lowest and of the highest barometer being indicated for each day. In the volume for 1880 of "Aus dem Archiv der Seewarte," the daily positions of the cyclonic centres for the first three months of 1878 are given, but the movement of maximum pressure is shown by a simple line without any indication of the position every twenty-four hours. Dr. Köppen has considerably improved on these plans. He has before him the daily charts for several weeks, and finds that for a number of consecutive days there is a general resemblance in the distribution of high and low pressure areas, the former almost stationary, the latter travelling along on the edges of the anticyclones. He selects the ruling type for the whole area of the charts, and then proceeds to represent the period of the type on one chart, the number of such periods in the twelve months ending with August 1884 being fifty-seven, ranging from three to eleven days each. The movements of the cyclones during the type are represented by lines joining the ascertained positions each day, and by a simple arrangement the lowest pressure and the force of the wind are represented daily. The anticyclones are treated differently, they are considered as practically stationary, and the isobar of 765 mm. (30·12 inches) being found on the charts every day, it has been adopted as the representative of the high-pressure systems. This isobar for the several days of the type produces a mean line which shows the average position of the anticyclone during the period. The maximum barometric values are shown near the centre, and also the direction in which the highest pressures moved, as in the volume already alluded to.

An examination of the results as shown by this method indicates that the question of storm tracking has been greatly simplified. Instead of twelve monthly charts full of tangled curves exhausting our patience to unravel them, we have about five for each month, the paths of disturbances during the prevalence of a type not varying greatly, and individual cases are followed without difficulty. The question of expense in lithographing the charts has apparently compelled Dr. Köppen to represent two, and even three, types on one chart, which tends to confusion; and if more of this kind of work is to be done, it will be well to strain a point to give each period by itself, so as not to perplex those who only occasionally deal with such charts. There are, however, several single periods to which a chart has been devoted, and a study of these only will suffice to convince us that an advance in the right direction has been made. Take the sixth and seventh charts representing the conditions between October 26 and November 1, and November 2 to 10, 1883, and the importance of the work is at once apparent. In the former the permanent anticyclone over the ocean is well south, while the European anticyclone covers all but the most northern parts of Scandinavia and Russia. The cyclones follow a well-marked path from America to Iceland and the White Sea. In the second case the Atlantic anticyclone is further north, and the European area has moved away to the eastward, and in keeping with these changes, the disturbances have also modified their directions. Speaking very generally, storm areas run parallel with the edge of the anticyclone. According to the position of the latter so do the cyclones advance, recede, or stand still. We see that land does not seem to offer any resistance to the advance of a storm area, the changes of direction in mid-ocean being quite as frequent as near the land. Tropical storms may either march due north, curve round by the American coast, or proceed to the western side of the Gulf of Mexico, and then cross the American continent to the Atlantic; but in each case we find the position of the anticyclone to govern the course followed. From a similar cause the rate of movement is also affected, varying quite as much on the level surface of the sea as in the midst of mountainous continents. In the chart for March 30 to April 11, 1884, the anticyclones over Europe, the Atlantic, Greenland, and America form a barrier allowing no means of escape for the disturbance which is seen to wind about from Davis Strait to the coast of Ireland and back again to the neighbourhood of its starting-point. The question of direction and rate, therefore, depends largely upon the position and stability of the anticyclones; and if we can in any way discover the resisting power of the latter we should no doubt greatly increase our ability to forecast changes. For the purposes of storm-warnings, it seems to be quite as necessary to know the conditions over Eastern as over Western

[1] "Vierteljahrs-Wetter-Rundschau an der Hand der täglichen synoptischen Wetterkarten für den Nordatlantischen Ocean des Dänischen Meteorologischen Instituts und der Deutschen Seewarte." Parts 1 to 5, September 1883 to November 1884, with 41 Charts. (Berlin: Mittler und Sohn, 1887-88.)

Europe, because it is on the existence or non-existence of anticyclonic areas over Russia that bad weather may either steer clear of our coasts, or pass clean over us and cause enormous damage to life and property.

Dr. Köppen's adaptation of composite portraiture for anticyclones will, when fully developed, doubtless lead to the discovery of principles which must be of considerable practical importance in our every-day life, and meteorologists should direct their attention to the discovery of some law which will indicate the approach of a change in the distribution of high barometer readings. At present we know absolutely nothing of what is taking place over the Atlantic out of sight of our own coasts, and the ordinary weather-charts cover such a small extent of North-Western Europe that they do not give us a fair idea of what the conditions are to the eastward. As the facts indicated become more fully known, we shall probably see an extension of the Weather Report area, and a corresponding improvement in forecasting.

The "Vierteljahrs-Wetter-Rundschau" appeared originally in various numbers of the *Annalen der Hydrographie und Maritimen Meteorologie*, the official publication of the Deutsche Seewarte, and are now reprinted in separate form.

NOTES.

THE members of the "Provisional Committee" appointed at the International Geological Congress in London, with reference to preparations for the next meeting of the Congress at Philadelphia, met at New Haven on Thursday, November 15. All were present except Dr. T. Sterry Hunt, who was confined to New York by illness. By vote, twenty-four members of the Permanent or Organizing Committee were appointed, as follows:—C. A. Ashburner, J. C. Branner, T. C. Chamberlin, G. H. Cook, J. D. Dana, W. M. Davis, C. E. Dutton, G. K. Gilbert, James Hall, A. Heilprin, C. H. Hitchcock, Joseph LeConte, Dr. J. Leidy, J. P. Lesley, O. C. Marsh, J. S. Newberry, J. W. Powell, J. R. Procter, N. S. Shaler, J. J. Stevenson, C. D. Walcott, R. P. Whitfield, H. S. Williams, Alexander Winchell. The Committee has power to add to its number. Dr. J. S. Newberry was appointed temporary Chairman. With this action, the duties of the Provisional Committee ended. The first meeting of the Permanent Committee will be held in Washington in the month of April. One of the publications presented to the recent session of the Congress in London was a voluminous Report on some important questions in American stratigraphical geology. We learn from an article in the December number of the *American Journal of Science*, by Prof. Dana, that, in his opinion, the views of the great majority of American geologists are not fairly represented in that Report. The Committee now appointed will certainly be regarded by geologists in Europe as a thoroughly representative one, which will, no doubt, take good care that the general body of geological opinion in the United States shall be adequately put before the world at the Philadelphia meeting.

ON Tuesday the completion of the ninth edition of the "Encyclopædia Britannica" was celebrated by a dinner given by Dr. W. Robertson Smith, the editor, in the hall of Christ's College, Cambridge. Upwards of a hundred contributors were present, and among them were many eminent men of science. Responding for "Science," Dr. Archibald Geikie said the old limits within which culture was confined had proved to be altogether too small for the progress of the present day. The soldiers of the republic of science had sometimes been accused of a strong desire to attack University culture and carry it by storm. For his part he wished that it might stand, but that no barrier should be interposed against the freest communion between the people inside and the newer and wider city around their borders.

AN Anthropological Congress is to be held at Vienna during August next.

AN important paper by Prof. Virchow, on "Land and People in Ancient and Modern Egypt," appears in the current number of the Transactions of the Berlin Gesellschaft für Erdkunde. It embodies some of the results of Prof. Virchow's ethnological researches during his recent visit to Egypt. It has hitherto been thought that the fellaheen of to-day are of exactly the same physical type as that of the most ancient known Egyptian population. Prof. Virchow, however, holds that the evidence afforded by the oldest sculpture, as well as by the skulls of the earliest period, tends to show that the primitive type in Egypt was brachycephalic, whereas the types which exist at the present time, and have existed for ages, are dolichocephalic and mesocephalic. Whether the change was produced by the influence of environment, or by the influx of new races, cannot, according to Prof. Virchow, be definitely determined by the evidence at present at our disposal; but, of the two views, the latter, he thinks, is the more probable.

THE inaugural lecture delivered before the University of Glasgow by Prof. Max Müller, as Lord Gifford's Lecturer in Natural Theology, has just been published by Messrs. Longmans, Green, and Co. In this lecture, Prof. Müller presents a most interesting account of the ideas which have regulated the work of his life. His conception of "the science of religion" will serve as the test, and, he hopes, the confirmation, of his theories relating to language, mythology, and thought.

THE New England Meteorological Society proposes to have a Loan Exhibition of Meteorological Apparatus, Photographs, &c., at the Institute of Technology, Boston, in connection with its fourteenth regular meeting in January 1889. The Society has issued a request for contributions.

THE Report of the Norwegian party of the International Polar Investigation contains the results of the observations which were made according to the programme decided upon at the Polar Conference at St. Petersburg, in August 1881. The observations were made at Bossekop in Alten, in lat. 69° 58′ N. and long. 23° 15′ E. of Greenwich. The first volume, issued in 1887, contains the astronomical and meteorological observations, and the second volume (Christiania, 1888) gives the results of the magnetic determinations and observations of auroræ. In the meteorological section, tables are given of the hourly readings of the temperature and humidity of the air, height of barometer, direction of winds and nature of clouds, extending from August 1882 to August 1883 inclusive, and concluding with monthly averages. In vol. ii. are given the records of the determinations of the magnetic declination and horizontal and vertical intensity. These were made fortnightly during the year, at intervals of five minutes during the day, so that the carefully-executed curves expressing the results of the observations are very detailed and convenient for comparison with the complete descriptions of auroral displays, the records of which are also contained in this volume. No doubt these results will be of great service in correlating auroræ with magnetic disturbances.

THE Royal Meteorological Society has published its "Meteorological Record" for the first quarter of this year, containing the monthly results of observations made at its stations, with remarks on the weather by Mr. W. Marriott. The Society commenced the organization of stations on a uniform plan in 1874, and these were supplemented by another class of stations, termed climatological, in 1880. Since 1881 the results have been published in a separate form under the above title. A map of the stations is issued annually, and shows that they are fairly well distributed, except in Wales. In addition to the monthly results, tables of daily rainfall are given for a number of stations, and of the

daily temperature and sunshine in London and the suburbs. The monthly values published by the Registrar-General are also appended, and the whole forms a valuable record of the meteorological statistics of England and Wales, issued well up to date.

AT the meeting of the French Meteorological Society on November 6, M. Lemoine presented a summary of the rainfall observations of the basin of the Seine in 1887. He stated that the rainfall was everywhere below the average; in the Department of the Seine-Inférieure the totals for the year were the lowest in a series of twenty-one years. M. Renou stated that the late M. Hervé-Mangon having expressed the wish that his observations made at Ste.-Marie-du-Mont should be published, Mme. Mangon had handed them over to him for publication at her expense. M. Renou presented a note on the temperature of October at Paris since 1757. He pointed out that during the last 130 years the month of October presented either a low or a high mean every twenty or twenty-five years. Means as low as that for October 1887, viz. 44°·1, were very rare. Since 1757 the lowest averages for October had occurred in 1784 (45°·3), and 1817 (45°·1).

BIOLOGISTS will be glad to learn that the posthumous works of the late M. Severtsoff are being issued by M. Menzbier, at Moscow, and that a new part has been added this year to the part which appeared in 1886. Severtsoff not only was a first-rate zoologist and explorer of unbeaten tracts in Turkestan; he was also a powerful thinker, and everything he wrote about the philosophy of zoology deserves attention. Unhappily, his frequent expeditions to Central Asia rendered it impossible for him to bring to an end the works of a general character which he was preparing. He had begun an "Ornithology of Turkestan," based upon his exceedingly rich collection of birds, which contains no less than from 12,000 to 13,000 specimens. This work will be completed by M. Menzbier, and it could not have been put into better hands. As for the two parts of his "Posthumous Works" (*Mémoires de la Soc. des Natur. de Moscou*, vol. xv. fascs. 3 and 5), they consist of two papers: one in German, on two insufficiently known species of Russian hunting hawks (*Hierofalco grebnitzky*, n. sp., and *Hierofalco uralensis*, Sev. et Menzbier); and the other, in French, on variations due to age of the Palæarctic *Aquilinæ*, and the taxonomic importance of those variations. The former contains, besides the description of the two species (with coloured plates), a sketch of the geographical distribution of the Icelandian, Norwegian, Uralian, and Labradorian species of *Hierofalco*. The second paper contains, first, a discussion of some principles of zoological classification, being an answer to Dr. Seebohm's reproach of having "too closely followed the steps of the elder Brehm." and of having aimed at "hitting the happy medium between 'lumpers' and 'splitters.'" This is followed by a discussion of the natural extent of the family of *Aquilinæ* (which, according to Severtsoff, must include only the three genera, *Aquila*, *Haliaëtos*, and *Milvus*); the geographical distribution of all known species of the *Aquilinæ*; and finally, the description of those species which Severtsoff had himself studied closely in the field,—special attention being given to the variations of coloration dependent upon the age of the individuals Seven beautifully coloured plates accompany the work.

WE have received the twelfth volume of the systematic Catalogue of the Museum of Natural History of the Netherlands. The present volume deals with Mammifers, and has been compiled by F. A. Jentink. No fewer than 5379 individuals, representing 900 species of Mammifers, are enumerated in this Catalogue. M. Jentink hopes that his work may be of service to zoologists by enabling them to see what rare or interesting species are to be found in the National Museum, the value of which, in this particular branch, has not hitherto, apparently, been sufficiently appreciated.

A PAPER on "Energy and Vision," by Prof. S. P. Langley, was read by abstract before the American National Academy of Sciences on April 19 last. This paper was printed in the November number of the *American Journal of Science*, and has now been separately issued. The writer does not profess any competence in physiological optics, and points out that his observations, and the conclusions reached from them, are both to be understood from the purely physical point of view. This being premised, he summarizes the paper in the following conclusions:—"The time required for the distinct perception of an excessively faint light is about one half-second. A relatively very long time is, however, needed for the recovery of sensitiveness after exposure to a bright light, and the time demanded for this restoration of complete visual power appears to be the greatest when the light to be perceived is of a violet colour. *The visual effect produced by any given, constant amount of energy varies enormously according to the colour of the light in question.* It varies considerably between eyes which may ordinarily be called normal ones, but an average gives the following proportionate result for seven points in the normal spectrum, whose wave-lengths correspond approximately with those of the ordinary colour divisions, where unity is the amount of energy (about $\frac{1}{1000}$ erg) required to make us see light in the crimson of the spectrum near A, and where the six preceding wave-lengths given correspond approximately to the six colours—violet, blue, green, yellow, orange, red.

Colour.	Violet.	Blue.	Green.	Yellow.	Orange.	Red.	Crims.
	μ	μ	μ	μ	μ	μ	μ
Wave-length	·40	·47	·53	·58	·60	·65	·75
Luminosity (visual effect).	1,600	62,000	100,000	28,000	14,000	1200	1

Since we can recognize colour still deeper than this crimson, it appears that the same amount of energy may produce *at least* 100,000 times the visual effect in one colour of the spectrum that it does in another, and that the *vis viva* of the waves whose length is $0·75^{\mu}$, arrested by the ordinary retina, represents work done in giving rise to the sensation of crimson light of 0·000000000000003 horse power, or about 0·001 of an erg, while the sensation of green can be produced by 0·00000001 of an erg."

A NEW and highly interesting method of obtaining gaseous carbon oxysulphide, COS, perfectly pure and in large quantities, has been discovered by M. Armand Gautier. The methods of preparing this gas already known are somewhat difficult to carry out, and the only effectual means of purifying it from the persistent presence of carbon disulphide vapour with which we have been hitherto acquainted, is by utilizing the fact that carbon disulphide is absorbed by triethyl phosphine, a most costly reagent. M. Gautier's new method is extremely simple. A large porcelain tube is partially filled with calcined kaolin, the purest variety of natural silicate of alumina, and heated to whiteness in a good furnace. The air having been first expelled by means of a current of carbon dioxide, a gentle stream of dry carbon disulphide vapour is allowed to slowly pass through the tube. The mixture of gases which issues from the tube is found to consist of a little over 60 per cent. of carbon oxysulphide, and about 35 per cent. of carbonic oxide, together with traces of carbon dioxide and sulphuretted hydrogen, and a slight excess of vapour of carbon disulphide. This mixture is now passed (1) through a flask half filled with iced water, in which is deposited the greater portion of the excess of carbon disulphide; (2) through a wash-bottle containing potash solution, which absorbs carbon dioxide and sulphuretted hydrogen; (3) through a solution of cuprous chloride in hydrochloric acid, which removes the carbonic oxide; (4) through an alcoholic 12 per cent. solution of aniline, which

takes up the last traces of carbon disulphide, with formation, according to Hofmann, of sulpho-diphenyl-urea, $CS(NH . C_6H_5)_2$; and finally (5) through an ordinary drying tube containing pumice and sulphuric acid. The gas which issues from the apparatus thus arranged is found on analysis, provided the most ordinary precautions are taken not to allow the passage of too rapid a stream, to consist of chemically pure carbon oxysulphide. As regards what happens in the kaolin tube, on allowing it to cool in contact with the mixture of gases and afterwards carefully breaking it, at the end from which the gas issued a quantity of brilliant white needles of silicon sulphide, SiS_2, are found partially obstructing the tube. In place of the kaolin is found a graphitic mass studded with very hard tolerably large crystals of a substance which evolves sulphuretted hydrogen in contact with moist air, and is decomposed by water with precipitation of gelatinous aluminic and silicic hydrates. This most interesting substance is in reality a sulpho-silicate of alumina, or a kaolin in which oxygen has been replaced by sulphur, thus opening up the wide prospect of the formation of a whole series of sulpho-silicates in which the oxygen of natural silicates is replaced by sulphur.

A WORK on the telephone, by Mr. W. H. Preece and Dr. Julius Maier, which has long been in preparation, will be published in the course of a week or two by Messrs. Whittaker and Co., as a volume in their "Specialists' Series." A work on manures will be published shortly in the same series. Its author is Dr. A. B. Griffiths, Principal of the School of Science, Lincoln. Mr. G. R. Bodmer has in the press a practical treatise on hydraulic motors, which will also form a volume of the "Specialists' Series."

THE Carpathian Club in Transylvania, which was founded in 1880, has now about 1600 members. Its object is to investigate the Transylvanian Alps, and to construct good roads and refuges. The Club intends to erect at Hermannstadt a Museum for its library, and for maps, plans, photographic views of the Carpathians, and ethnological and natural history objects.

THE Liverpool Science Students' Association has issued its Report for the session 1887-88. According to the Committee, the condition of the Society, as regards both the number of its members and the character of its work, is eminently satisfactory. The papers read at the evening meetings were, we are told, "of a high character, evidencing much careful observation and patient investigation."

A REPORT from Elba states that the whole of the island is infected by Phylloxera. In Toscana the efforts to check the plague have as yet proved unsuccessful. The insect has also made its appearance at Parmi, in Calabria, at Novara, and at Cervo in Liguria. Reports from the neighbourhood of San Remo and from Lombardy state that the infected areas are constantly increasing.

DURING the last summer, Washington and other eastern cities of the United States were exceptionally free from the attacks of "shade-tree pests." Elm-leaf beetles were not nearly so numerous as usual. In recording this fact in *Insect Life*—a useful publication lately started by the United States Department of Agriculture—the writer refers to "an occurrence which shows how careful one must be in drawing conclusions from experiments to destroy insects." "Counting," he says, "upon the ordinary appearance of the elm-leaf beetle, we sprayed the trees in our garden with London purple early in the summer, and as no damage was done, we were quite of the opinion that the spraying had been a success until, later, we noticed that unsprayed trees were quite free also. In the same way a gentleman came to us toward the end of the season and informed us that he had completely protected his trees, by spraying the grass under them with Paris green, his trees for the first time in several years having retained the verdure of their foliage."

AT a recent meeting of the Linnean Society of New South Wales, Mr. C. W. De Wis read a paper presenting "A Glimpse of the Post-Tertiary Avi-fauna of Queensland." He described such bird-remains as can with confidence be referred to known genera, from the Chinchilla deposits, Darling Downs, Queensland. The fossiliferous beds, which have been exposed by floods in the banks of the Condamine River, have yielded the remains of mollusks, fresh-water fishes, alligators, turtles, and terrestrial vertebrates; whence it may be inferred that the locality was once the site of a densely populated water-course or basin. In keeping with this it might have been anticipated that the birds whose remains have so far come to light would belong for the most part to tribes which haunt the margins or explore the waters of lakes and rivers. And this turns out to be the case, for, with one or two more or less doubtful exceptions, the nine species described are referable to birds of no higher grade than the old order Grallatores, the majority of them belonging chiefly to the Anseres and Rallidæ.

THE last issue of the *Mittheilungen* of the German Asiatic Society of Japan (Heft 39, Band iv.) contains a long account of the remote Chinese province of Kansu, by Herr von Kreitner, who is known to many readers as a member of the Szchenyi Expedition to the borders of Tibet about twelve years ago, and the author of an account of the explorations then made, entitled "Im Fernen Osten." The writer describes the geography of the province in three sections: (1) North-Western Kansu, belonging to the Gobi and Shamo deserts; (2) the central and north-eastern districts, which are drained by the Hoang-ho or Yellow River; and (3) Southern Kansu, belonging to the Yang-tsze drainage area. One feature of the paper is a picturesque account of the loess districts of the province. Prof. Fesca describes briefly two works of his on Japanese agriculture, and the agricultural capacities of the country, which have recently appeared. A third paper, also short, contains the results of an investigation into the chemical changes produced in tea by the process of "firing," a species of roasting which the leaf undergoes after it is picked, and before shipment to Europe.

IN the signature of the letter entitled "The Pasteur Institute," printed in NATURE last week, for Parky*er* read Parky*n*.

THE additions to the Zoological Society's Gardens during the past week include two Philippine Paradoxures (*Paradoxurus philippensis*) from the Philippine Islands, presented by Mr. G. P. Ogg; a Brazilian Tapir (*Tapirus americanus* ♂) from the Province of Parana, South America, presented by Mr. Anthony Taafe; a Long-fronted Gerbille (*Gerbillus longifrons*) from Western Asia, presented by Mr. Lionel Hanbury; a Meyer's Parrot (*Pæocephalus meyeri*) from East Africa, presented by Dr. Hugh Eaton, F.G.S.; two Common Quails (*Coturnix communis*), European, presented by Mr. W. H. St. Quintin, F.Z.S.; a Common Guillemot (*Lomvia troile*), British, presented by Mr. E. Hart, F.Z.S.; a Moorish Gecko (*Tarentola mauritanica*) from the South of France, presented by Mr. J. C. Warbury; an Indian Crocodile (*Crocodilus palustris*), a Hawks-billed Turtle (*Chelone imbricata*) from the Philippine Islands, presented by Captain J. Sommes; a Black Salamander (*Salamandra atra*), European, presented by Mr. G. A. Boulenger, F.Z.S.; a Bald-headed Chimpanzee (*Anthropopithecus calvus* ♀) from the Gaboon, three Dwarf Chameleons (*Chamæleon pumilus*) from South Africa, deposited; a Molucca Deer (*Cervus moluccensis*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

COMET 1888 *e* (BARNARD, SEPTEMBER 2).—The following ephemeris for this comet for Greenwich midnight is in continuation of that given in NATURE, vol. xxxix. p. 114:—

1888.	R.A. h. m. s.	Decl. ° ′	Log Δ.	Log *r*.	Brightness.
Dec. 15	1 4 21	7 41·2 S.	0·1390	0·2810	8·7
17	0 56 52	7 43·1			
19	0 49 59	7 43·4	0·1654	0·2776	7·8
21	0 43 38	7 42·4			
23	0 37 47	7 40·1	0·1916	0·2744	7·0
25	0 32 24	7 36·9			
27	0 27 29	7 32·8 S.	0·2170	0·2715	6·3

The brightness on September 2 has been taken as unity.

The spectrum of the comet presents no very interesting feature, as it is mainly continuous, with but little evidence of the bright hydrocarbon bands.

Y CYGNI.—Although it is only just two years since Mr. Chandler discovered this variable, and but comparatively few minima have therefore yet been observed—the fewer that the star seems to have been unaccountably neglected by European observers—yet some strange and strongly-marked anomalies have already been observed in its period. Although the light-curve is of such a shape as to enable the minima to be determined with much precision, the variations in brightness proceeding with relatively great rapidity, and Mr. Chandler had therefore believed that the period he had deduced from his 1886 and 1887 observations could not be more than a second or two in error, he found, when the star came again under observation in the spring of 1888, that the ephemeris required a correction of four or five hours, and this difference increased until, in the October just past, it had amounted to nearly seven hours. Dividing all the observations into five groups, they give the following values for the period:—

d.	h.	m.	s.
1	11	56	31·8
		57	45·3
		58	19·5
		58	30·9

The observations from which these periods have been deduced include five minima determined by Mr. Sawyer, three by Mr. Yendell, and thirteen by Mr. Chandler himself. Using his own observations alone, he has roughly represented them by the following elements: 1889 January 25, 5h. 39·6m. (G.M.T.), + 1d. 12h. 0m. 0·12s. $(E - 519)$ + 0·24s. $(E - 519)^2$; the elements being referred to epoch 519 on account of the convenience of the period at that time being so nearly commensurate with a solar day. But these elements leave residuals far too large to be regarded as errors of observation, whilst the lengthening of the period, half a second between two successive recurrences, is entirely unparalleled in amount by the irregularities in other Algol variables. Mr. Chandler considers that this change is far more likely to be periodic, and of short period, than secular, and it is therefore specially to be desired that observers will follow it with all attention, for the complete knowledge of its changes must throw much light on the whole subject of variation of the Algol type. At present the minima occur soon after sunset, for England, on December 17, and every third following day, and shortly before sunrise on December 19, and every third following day. It is to be hoped that English observers will give a most persistent attention to this star, now so clearly a most important one.

RECENT SKETCHES OF JUPITER.—Vol. xlix. of the *Mémoires couronnés* of the Royal Academy of Sciences of Belgium, contains a valuable series of observations of Jupiter by Dr. F. Terby, of Louvain. This series, which contains his observations from 1882 to 1885, is in continuation of a former memoir, which appeared in vol. xlvii. of the same publication, and is soon to be followed by a third containing the results of his work in 1887. In this present memoir Dr. Terby has made some first efforts towards the identification of details on the surface of Jupiter in successive rotations, a work which he considers he has been able to carry on more successfully in his third series. The present memoir is illustrated by 100 sketches of the planet, which, if of no great beauty or minuteness of detail, are very creditable when the smallness of the telescope used—only 3½ inches aperture—is borne in mind, and are valuable from their number and the completeness of the series which they form. The 1887 observations were made with Dr. Terby's new telescope of 8 inches aperture, which has given excellent proof of its good quality.

On one occasion (1884 February 16) Dr. Terby was fortunate enough to watch the shadow of the first satellite pass over a bright white spot. The shadow lost none of its blackness in the transit, showing that the white spot was in no perceptible degree self-luminous.

85 PEGASI.—Some recent observations which Mr. Burnham has obtained of this close and difficult double, discovered by him in 1878, have enabled Mr. Schaeberle (*Gould's Astronomical Journal*, No. 185) to compute an approximate orbit, from which it appears that the star has a period of 22·3 years, and an eccentricity of 0·35, and that it passed through periastron at the beginning of 1884. The other elements are—

$$\pi - \Omega = 70°·3 \quad \ldots \quad i = 68°·6$$
$$\Omega = 306°·1 \quad \ldots \quad a = 0''·96$$

From observed position-angles and distances of the third star, C, the following result has been obtained for the relative proper motion of 85 Pegasi, viz. annual motion being 1″·305 and its direction 140° 20′·4, or in R.A. and Decl., $\Delta\alpha = + 0''·833$; $\Delta\delta = - 1''·005$. The comparison star, C, would appear to have a slight proper motion also, as these values differ somewhat from those obtained for 85 Pegasi by Argelander, Mädler, and Brünnow.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 DECEMBER 16–22.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on December 16

Sun rises, 8h. 3m.; souths, 11h. 56m. 7·7s.; sets, 15h. 50m.: right asc. on meridian, 17h. 38·3m.; decl. 23° 22′ S. Sidereal Time at Sunset. 21h. 33m.

Moon (Full on December 18, 11h.) rises, 15h. 3m.; souths, 22h. 48m.; sets, 6h. 43m.*: right asc. on meridian, 4h. 32·5m.; decl. 18° 23′ N.

Planet.	Rises. h. m.	Souths. h. m.	Sets. h. m.	Right asc. on meridian. h. m.	Declination on meridian. ° ′
Mercury..	7 34	11 26	15 18	17 8·0	23 34 S.

GEOGRAPHICAL NOTES.

GREAT activity is still being displayed by German explorers in the interior of Togo-land. Captain C. von François has brought to a successful termination his journey into the country confined within the great bend of the Niger. The route taken by him was as follows: viz. Kpandu, Salaga, Jendi, Gambaga, and then across the upper course of the Volta at Bupere (the river at this spot, though more than 80 yards broad, is no longer navigable). From this point he arrived on April 19 last at Surma (11° 28′ N. lat.) in the country of Mosi. He afterwards made an excursion from Gambaga to the south-west by way of Nantong to the River Volta, and returned to the coast through Adeli. In the latter place he met Dr. L. Wolf, who founded a station there on the Adado Mountains in the beginning of May, having travelled to Adeli through the eastern part of Togo-land. Dr. Wolf has, with the aid of a mercurial barometer, been able to determine numerous altitudes with greater accuracy than any measurements previously made in this part of Africa. It appears from his results that Dr. Henrici has considerably over-estimated the height of the Agome Mountains. Herr von Puttkamer, the Imperial Commissioner, made in March an excursion into the region of the French Protectorate as far as the lower course of the Mono, and then explored the country of Agotime up to the foot of the mountains. All these travellers agree in stating that the prospects of the interior of Togo-land are very favourable, both as regards agriculture and commerce. The climatic conditions of these uplands are much more favourable than those of the coast.

THE last issue of the *Bollettino* of the Italian Geographical Society, which is a double number for October and November, publishes an account by Dr. Leopoldo Travesi of an expedition he made last November to the almost unknown district of Jimma (Jimma-Kakka, Jimma Abba-Jifar) on the debatable borderland between Abyssinia and Kaffa. Jimma constitutes a petty Mohammedan State tributary to Menelek, King of Shoa, in the Upper Valley of the Ghibeh, which is an important head-stream of the Gugsa, and which had hitherto been crossed only by one European, Travesi's fellow-countryman, Cecchi. Through fear of "annexation" or "protection," Europeans are jealously excluded, and Travesi only succeeded in penetrating into the country by joining the suite of its ruler, Abba-Jafir, who was returning from a visit to his suzerain, King Menelek. Jimma forms a deep upland valley over 6000 feet above sea-level, about 40 miles long and 10 broad, and inhabited by an extremely mixed population, in which the Abyssinian, Galla, and Negro elements are intermingled in diverse proportions. Hence the great variety of types, and colours ranging from the relatively fair and regular Hamitic to the dark and nearly pure Negro, as well illustrated by the numerous photographs Travesi succeeded in obtaining, and eight of which are here reproduced. The penal code of Jimma is remarkable for its simplicity, most offences being punished by "banishment," which is here a euphuistic expression for "slavery." Hence to the traveller's question, "What do you do with your thieves and other criminals?" the prompt reply invariably was "We drive them from the country," meaning "We sell them." Had Travesi been allowed to penetrate a little further south, he would have solved the problem of the Juba and Sobat (White Nile) water-parting. As it was, he was able, from native report, almost to satisfy himself that the Gugsa, here called the Uma and elsewhere the Abula, flows, not west to the Nile basin, but south-east to Lake Abbala, which is known to be in the Juba basin. Consequently the Gugsa may be regarded as the chief head-stream of that river. He also heard of d'Abbadie's Mount Wosho, here however called *Woso*, which lay away to the south-east, and to describe the altitude of which the natives exhausted the language of hyperbole. They could not exactly say where it was, except that the country was called Am'ca (?), but they knew quite well it was the highest mountain in the world, lost in the skies, &c. The Wosho, whose existence was lately imperilled by certain vague reports, seems thus, at all events, "rehabilitated."

ELECTRICAL NOTES.

THE magnetic elements for Paris for 1888 are—

Declination	15° 52′ 1″
Dip	63° 14′ 7″
H	0·19480
V	0·42245
Total force	0·46520

SORET (*Arch. des Sciences*, April 1888) has reproduced Oliver Lodge's experiment on the dissipation of fog on a small scale by placing a platinum cup, containing water in a boiling condition, by a Bunsen flame in connection with one pole of an influence machine and a point above the water in connection with the other pole. When the machine is not at work, so-called steam ascends undisturbed, but when the machine is excited the clouds whirl and move about in a flame-like fashion, until the vapour disappears entirely. The experiment is made in a dark room, and the cup is illuminated by a beam of electric light.

C. L. WEBER (*Ann. Wiedemann*, xxxiv. p. 576) has made some interesting observations on the variation of the resistance of alloys of tin-lead and tin-bismuth at their period of fusion. A considerable and rapid increase of resistance is observed as the fusing-point is reached, and it is the more marked the simpler the composition of the alloys. Pb_2Sn behaves like pure tin. The tin-bismuth alloys are very irregular, for the specific resistance of bismuth falls as the point of fusion is reached.

VON OETTINGEN (*Ann. Wiedemann*, xxxiv. p. 570) has been repeating his old experiments on the oscillatory discharges of Leyden jars, and he has obtained some admirable photographs of sparks. They give periods of oscillations varying from 19 to 39 millionths of a second.

THE use of Gassner's dry cell is making great progress in Germany. In the latest form hydrated ferric oxide is used as the depolarizer. Ferric oxide is said to abandon all its oxygen in presence of sal ammoniac.

A NOVEL trial is about to commence in Philadelphia. It is to decide the question whether electricity is a condition or a thing, and whether it is something which is manufactured.

A CONGRESS OF ELECTRICIANS will be held in Paris, in 1889, under the presidency of M. Mascart, and under the auspices of the International Society of Electricians. It is proposed to hold the meeting in September, but the British Association meeting in Newcastle will prevent many English electricians from being present.

THE term "therm," in place of *calorie*, for the unit of heat in the C.G.S. system has not met with general approbation, as the other names applied to these units have done. It was, perhaps, hastily accepted; but has it occurred to the dissentients that it might be dispensed with altogether, and that the unit of work "Joule" answers all the purpose of a unit of heat? There are 4·2 *Joules* in a *therm*. They are of the same dimensions, and really indicate the same physical quantity, viz. the mechanical equivalent of heat. Calorie will, however, perhaps hold its own, now that the C.G.S. system is so generally adopted. The only reason that led to the acceptance of the therm was the confusion arising from the kilogramme-degree, as well as the gramme degree, being called a calorie, but the former is fast going out.

THE ANNIVERSARY OF THE ROYAL SOCIETY.[1]

IN the month which intervened between our last anniversary and the end of the year, the Society lost four of its Fellows. In addressing the Fellows last year, I referred to the loss which science had sustained through the death of the illustrious Kirchhoff, and before three weeks were out, one followed him to the grave whose researches on the connection between the emission and absorption of radiant heat and light were closely akin to those of Kirchhoff. I refer to Balfour Stewart, who, shortly after landing in Ireland, whither he had gone to spend the Christmas with his family, was suddenly carried off after only a few hours' illness, shortly after he had entered on his sixtieth year. His name is widely known on account of his scientific work in heat, magnetism, and solar physics. He has been a member of the Council, and the Rumford Medal of the Society was awarded to him for the particular research to which I alluded at the outset. The other three of our ordinary Fellows

[1] Address of the President, delivered at the Anniversary Meeting, on November 30.

who died before the month was out were all far advanced in years. Two of them were eminent in the medical world, Sir George Burrows and Dr. Arthur Farre, both of whom served on our Council. Early in the year we lost one of our Fellows, who, while not a man of science, was eminent in literature and jurisprudence. While our ranks are mainly recruited from men of science, we gladly welcome among us men who, like Sir Henry Sumner Maine, have proved their ability and earned their distinction in other branches of knowledge; whose connection with us we look on as honourable to the Society, while, as the very fact of their joining us shows, they regard the Fellowship as honourable to themselves. Admiral Sir Cooper Key, who was highly distinguished as a naval officer, and was at one time Director of the Royal Naval College at Greenwich, was another who served on the Council. Philip Henry Gosse, who died at an advanced age, is well known for his charming popular works on natural history. These are some of the Fellows on the home list who died since the last anniversary; but, besides these, we have lost no less than three of our foreign members. Prof. Anton de Bary, so well known for his researches on the Cryptogams, and the eminent naturalist, Prof. Asa Gray, who not very long ago was over in this country, both died in January. Comparatively recently we have lost Prof. Clausius, so eminent as a physicist, especially in the department of thermodynamics.

The year of the Society which terminates to-day has shown no flagging in scientific activity. Since the last anniversary, thirty-three memoirs have been published in the Philosophical Transactions, containing a total of 1010 pages and 91 plates. Of the Proceedings, nineteen numbers have been issued, containing 1008 pages and 17 plates. In addition to this, a monograph of the Horny Sponges of Australia, by Dr. R. von Lendenfeld, which was accepted for publication by the Council, and which when completed will extend to about 1000 pages, is now nearly through the press.

A large amount of work connected with the Library has been done since the last anniversary. A special effort has been made to complete imperfect series of scientific periodicals; and by means of exchange, or by the generosity of our corresponding Societies, some hundreds of deficient numbers have been obtained. The Lists of Institutions entitled to receive gratis the Philosophical Transactions and Proceedings have also been carefully revised by the Library Committee.

In December last, Mr. Arthur Soper was engaged as a special Assistant to continue the formation of the Shelf-Catalogue, and the revision of the Catalogue of MSS., and other work. The Shelf-Catalogue of the Upper Library is now completed—a work involving the rearrangement or removal to the lower stories of several thousands of volumes. Considerable progress has been made in collating and cataloguing the Archives and other manuscripts belonging to the Society, and an instalment of slips have been written towards a Catalogue of the Miscellaneous Literature in the Library.

In the course of this work many duplicate scientific books, and literary works of little value to the Society, have been thrown out, and these have been presented, by order of the Council, to the libraries of the Universities and some of the chief scientific Societies.

The cataloguing of the titles of scientific papers for the decade 1874 to 1883 is now complete, and the work is ready for the press. The amount of matter is estimated to require, if printed, three quarto volumes of the usual size. The extraction of the title, the preparation of the work for the press, and the correction of the proofs of this work, which is really of international importance, has all along been done at the sole charge of the Royal Society; but the printing of the volumes which have already been published has been done at the Stationery Office, by the authority of the Lords of the Treasury, and the proceeds of the sale have been paid in to the Treasury. The Council have applied to the Lords Commissioners of Her Majesty's Treasury to sanction the printing of the last decade in a similar manner, and it is hoped that the application may be favourably entertained.

In the year 1882 a change was made in the amount and mode of administration of the grant which for a considerable time before had been voted annually by Parliament for scientific research. Since that year the annual grant has been one of £4000, which has been administered by the former Government Grant Committee, with the addition of certain *ex-officio* members, mostly the Presidents of certain scientific Societies. Meetings of this large Committee, consisting usually of about fifty members, have been held twice a year, and the various applications for aid from the grant to enable the applicant to carry out investigations explained by him, have been previously discussed in meetings of three, or latterly two, Sub-Committees, into which the whole Committee was divided, and then submitted to the General Committee for confirmation or modification.

In the discussion of these grants, the Government received the benefit of the gratuitous services of a large number of men of the highest distinction in science. In the large Sub-Committees, however, it necessarily happened that of the members present only a fraction would be likely to be conversant with the particular branch of science to which any particular application belonged; and the Council thought that the time of the members might be economized, and at the same time a more efficient discussion of the grants secured, by arranging the applications under a number of subdivisions, and assigning the discussion of these to a corresponding number of Boards formed out of the General Committee. It was thought that a good deal of the discussion of the applications in the several branches might be carried on by correspondence among the members of the respective Boards, so that one or two meetings of each Board might suffice. If some trouble were thus saved to the members of the Committee in regard to personal attendance at long meetings, there would probably be more expenditure of time in the way of correspondence, and it was thought that one meeting of the General Committee in the year would in most cases suffice. To meet pressing cases in the interval, it was suggested that a limited sum might be placed by the General Committee at the disposal of the Council of the Royal Society. There are further provisions for forming a reserve fund of not more than £2000 to meet special objects involving unusual expenditure, and for holding in reserve out of the money available for any one year enough to meet annual grants of limited amount made for a period not exceeding three years, the future grants being contingent on the receipt by the Committee of satisfactory evidence of progress in the inquiry. The new regulations, of which I have merely given a slight sketch, have been communicated to the Treasury, and will come into operation next year.

The Krakatão Committee have now completed their work, and the volume which is the outcome of their labours is in the hands of the public. The Society is much indebted to those Fellows and other gentlemen who discussed and reported on the different subjects into which the whole inquiry was divided, and to Mr. Symons, who was the first to propose that the materials should be collected, and to whose unwearied labour as Chairman of the Committee, director of the correspondence, and editor of the volume the successful accomplishment of the undertaking is largely due. The work has been favourably noticed in more than one quarter. A comprehensive and digested account of that extraordinary volcanic explosion, remarkable both for its magnitude and the striking disturbances and other phenomena attending or following it, is now placed within easy reach of the ordinary reader, and will go down to posterity; whereas, had the various accounts remained in their isolated form, they would many of them have perished, and the remainder could not have been brought together without a most laborious search. It must be a great satisfaction to my predecessor in this chair to remember that he urged upon the Council the importance of collecting the facts before the materials should have become dissipated, and while the freshness of men's recollection of the event kept up a lively interest in all that belonged to it.

The Royal Society is in possession of some important standards for the safe keeping of which we are responsible. Parliamentary copies of the standard yard and standard pound have been intrusted to our custody; and we have also a standard measure of length known as Sir George Schuckburgh's scale, with reference to which the length of the seconds pendulum for Greenwich has been determined by Kater and Sabine. This length, as determined by experiment, has been defined with reference to the interval from the 0 to the 39- and 40-inch graduations on the scale; but no exact comparison has hitherto been made between the length of this portion of the scale and the national yard, and such a comparison is no easy matter. It happens that Commandant Deforges has been engaged in determining the length of the seconds pendulum at Greenwich with reference to the French standard metre, and just before his return to Paris he came to our meeting, and offered to take charge of the scale, bring it with him to Paris, and there determine the length of the part of the scale used by Kater and Sabine with reference to the metre, for doing which he has all the requisite appliances; and as we know the ratio of the metre to the yard,

the length of the seconds pendulum as determined by Kater and Sabine would thus be known accurately with reference to the standard yard. It seemed to me that so important a scale should hardly be sent away, even though in the care of so experienced a physicist, without the authority of the Council, and without an outer case being made for its box, which there was no time to get ready. The authority of the Council has since been obtained, and it fortunately happens that one of the assistants at the Greenwich Observatory is going to Paris, who will take charge of the scale. Thus by the kind proposal of Commandant Deforges, we may shortly hope to have an authentic comparison of the length of the seconds pendulum as measured by Kater and Sabine with the standard English yard.

At the time of the anniversary last year, some of the reports of the observers who went to Grenada to observe the total solar eclipse of August 1886 had been seen in, and I mentioned that it seemed desirable, for convenience of reference at a future time, that the different reports should come out together, instead of being published in a scattered form, provided at least that the waiting for the later reports should not cause too much delay. I regret to say that the completion of the reports has been delayed in part by the illness of one of the observers, but I have every hope that they will all be in by Christmas, and I do not anticipate that any long time will elapse before they will be in some form in the hands of the public.

The time is well within our recollection when the occurrence of the solar prominences seen in total eclipses first attracted the attention of astronomers, and when for observations bearing on their nature we had to wait for the rare and brief glimpses which, clouds permitting, were afforded by total eclipses. Now, however, thanks to the method of observation devised independently by Lockyer and Janssen, they may be studied at any time. It would obviously be a great advantage if a similar study could be made of the corona; for though we cannot expect to obtain a picture of it equal to that which may be got during a total eclipse, yet, if a fairly good picture could be obtained from time to time, we might thereby be enabled to learn more about the history of its changes than could be got by observations extending over a lifetime if restricted to total eclipses. Some observations were made during the partial phases of the last total eclipse with the view of throwing light on the prospect of success. Notwithstanding the unpromising nature of the results obtained, I have reason for hoping that the desired object may yet be accomplished.

In addressing you last year, that year which will be memorable as the Jubilee of the reign of our beloved Sovereign, I alluded briefly to the progress which science had made in the last half-century, and ventured to indicate one or two directions in which it seemed to me possible that a very great addition to our physical knowledge might some day be reached. I will not to-day venture to look so far ahead; but the mention of a total eclipse leads me to refer to some theories now before the scientific world which are likely to undergo full discussion and further examination in the near future, with the probable result of a pretty general agreement as to their acceptance or rejection.

It is now many years since Dr. Huggins discovered the peculiar character of the spectra of the nebulæ, spectra which he found to consist mainly of bright lines, indicating that what we see is an incandescent gas. The natural supposition to make at the time was that those distant masses of matter consisted of incandescent gas, of which the luminosity was in some way kept up, probably as a result of condensation. But the researches of Mr. Lockyer, as described by him in the Bakerian Lecture which he delivered last spring, and in part in a previous paper communicated shortly before the last anniversary, have led him to take a different view of the constitution of nebulæ. According to the theory advanced by him, the mass of a nebula consists mainly of meteorites, which are constantly coming into collision here and there; and the glowing gas the existence of which the spectroscope reveals, is merely a portion of the matter, volatilized by the heat of collision. According to the former view therefore, the nebula consists of glowing gas, not yet condensed into a solid or liquid form, possibly in a oondition even more elementary than that of the so-called elements that we know on earth; according to the latter it consists mainly of discrete portions of solid matter, and the glowing gas does not consist of the same matter permanently glowing, but is continually supplied afresh by fresh collisions.

A similar theory is applied to explain the self-luminosity of the nucleus, and sometimes the very root of the tail, of comets. A comet is regarded as a swarm of meteorites, moving in orbits not greatly differing from one another; and as the swarm approaches the sun collisions become more frequent, and individually more potent, from an increase in the velocities, differential as well as absolute; and a portion of matter is volatilized and rendered incandescent. As to the tail, the theory long ago suggested by Sir John Herschel has always seemed to me by far the most probable of those that have been advanced—namely, that it is due to the propulsion of excessively attenuated matter, owing to a repulsive force, probably of electrical origin, emanating from the sun. This view seems to be adopted both by Mr. Lockyer and Dr. Huggins; and the latter gentleman, in an earlier Bakerian Lecture, has suggested a new theory of the corona—the corona as distinguished from the prominences—namely, that it is not projected from the sun by molar forces due to the tremendous state of turmoil in which we have very strong reason for believing that the matter composing the sun exists, but of matter actually propelled from the sun by a repulsive force in the manner of the tails of comets.

Daring as some of these speculations may appear to be, there seems a great deal to recommend them, and the whole subject is one of extreme interest at the present day.

But I must not take up your time longer by dwelling on so special a subject; I proceed to matters more particularly connected with the occasion on which we are assembled.

The Council have awarded the Copley Medal of the year to my predecessor in this chair, Mr. Huxley, for his investigations on the morphology and histology of vertebrate and invertebrate animals, and for his services to biological science in general during many past years. These subjects lie so entirely out of the range of my own studies that I need hardly say that in attempting to give some idea of the more salient features of his investigations I am dependent upon the kindness of biological friends.

During the fifteen or twenty years which preceded the publication of Darwin's famous work, the "Origin of Species," the views and methods of comparative anatomists underwent a most marked change. Without that change, biologists would have been far less prepared to accept Mr. Darwin's work, and, what is even more important, would have been unprepared to make use of that work as a light enabling them to carry on the remarkable researches which have so brilliantly characterized the progress of biology during the last quarter of a century. That change was effected chiefly by the labours first of Johannes Müller, and subsequently of Huxley in this country, and of Gegenbaur in Germany. The labours of these men opened out the right road of morphological inquiry. It is not, perhaps, too much to say that Mr. Huxley's treatment of his subject in his "Morphology of Cephalous Mollusca" was to many young morphologists little short of a revelation, and all his other works of the same period, such as that on the Hydrozoa and on Tunicates, and, later still, his treatment of the Vertebrate skull and skeleton, and Arthropoda, produced in varying degree a like effect.

Closely allied to, or rather forming part of, his morphological labours, are his numerous palæontological researches, carried out for the most part while he was Palæontologist to the Geological Survey, researches characterized by the same clear morphological insight, researches which have been as profitable to animal morphology as useful to the geologist. The most important are perhaps those on the remarkable reptiles of the Elgin Sandstones and on the Dinosauria; but many others have great value, and his anniversary address to the Geological Society, in 1870, made its mark.

Though his career has been in the main that of a morphologist, he has through the common ground of histology given considerable help to physiology. An early paper by him "On the Cell-Theory," did much to clear away erroneous notions concerning the relations of structure to the actions of living beings. His article on "Tegumentary Organs" was a great step onward as regards both morphology and histology, and still remains a classical work; while, by other papers and in various ways, he has contributed to the progress of histology and physiology.

But, however important Mr. Huxley's original contributions to the advancement of our scientific knowledge have been, we should form a very inadequate idea of his benefits to the cause of science if we did not bear in mind also his singular ability and effectiveness as an expositor of science to the people, and the powerful influence he has exerted in the improvement of the teaching of

biology in its widest sense in this country. Indeed, it is not too much to say that the remarkable improvement which has taken place within the last few years must be ascribed either directly or indirectly to his influence, and has been in many cases due to his initiation.

The Rumford Medal has been awarded to Prof. Pietro Tacchini for important and long-continued investigations, which have largely advanced our knowledge of the physics of the sun.

Prof. Tacchini occupies a foremost place among those who have paid special attention to the physics of the sun. Since 1870 he has unceasingly observed, first at Palermo, and afterwards at Rome, the solar prominences. The information at our disposal at the present time, both as regards their distribution, their spectra, and the changes which take place in them, and their connection with other solar phenomena, rests to a large extent upon his individual efforts. His memoirs on this subject are very numerous. He has been engaged in the observation of four total solar eclipses, and from some of the phenomena therein observed has drawn the important conclusion that many of the so-called prominences are really descending currents.

A Royal Medal has been awarded to Sir Ferdinand von Mueller for his long services in Australian exploration, and for his investigations of the flora of the Australian continent.

For more than forty years von Mueller has been working, without intermission, at scientific botany and its practical illustrations. As a botanical traveller and collector, he has, to quote the words of Sir Joseph Hooker, "personally explored more of the Australian continent than any other botanist, except Allan Cunningham." No one has investigated the Australian flora and the geographical distribution of its components with so much perseverance and success, and no one has enriched our herbaria, laboratories, and gardens with materials for study to so great an extent. The eleven volumes of the "Fragmenta Phytographiæ Australiæ" contain the descriptions of a great series of new plants, and the unrestricted communication of his collections and observations to the late Mr. Bentham rendered possible the preparation of the "Flora Australiensis," in seven volumes, the only account of the vegetation of any large continental area which has at present been completed.

He has especially devoted himself to the elucidation of the most difficult though most characteristic groups of the Australian flora; and as a result of his labours in this direction, his "Eucalyptographia" may be more particularly mentioned, a work which will always be the standard of nomenclature for the intricate genus *Eucalyptus*. Of a similiar character are his descriptions and illustrations of the "Myoporineous Plants of Australia," and his "Iconography of the Genus *Acacia*." To him is also due the foundation of the Government Herbarium at Melbourne, the first great botanical collection formed in the southern hemisphere, and the future centre of all scientific work on the Australasian flora.

A Royal Medal has been awarded to Prof. Osborne Reynolds for his investigations in mathematical and experimental physics, and on the application of scientific theory to engineering.

Prof. Reynolds was among the first to refer the repulsion exhibited in that remarkable instrument of Mr. Crookes's, the radiometer, to a change in the molecular impact of the rarefied gas consequent upon the slight change of temperature of the movable body due to the radiation incident upon it; and in an important paper published in the Philosophical Transactions for 1879, he deduced from theoretical considerations the conclusion that similar phenomena might be expected to be observed in bodies surrounded by a gas of comparatively large density, provided their surfaces were very small. He verified this anticipation by producing on silk fibres, surrounded by hydrogen at the atmospheric pressure, impulsions similar to those which in a high vacuum affect the relatively large disks of the radiometer.

In an important paper published in the Philosophical Transactions for 1883, he has given an account of an investigation, both theoretical and experimental, of the circumstances which determine whether the motion of water shall be direct or sinuous, or, in other words, regular and stable, or else eddying and unstable. The dimensions of the terms in the equations of motion of a fluid when viscosity is taken into account involve, as had been pointed out, the conditions of dynamical similarity in geometrically similar systems in which the motion is regular; but when the motion becomes eddying it seemed no longer to be amenable to mathematical treatment. But Prof. Reynolds has shown that the same conditions of similarity hold good, as to the average effect, even when the motion is of the eddying kind; and moreover that if in one system the motion is on the border between steady and eddying, in another system it will also be on the border, provided the system satisfies the above conditions of dynamical as well as geometrical similarity. This is a matter of great practical importance, because the resistance to the flow of water in channels and conduits usually depends mainly on the formation of eddies; and though we cannot determine mathematically the actual resistance, yet the application of the above proposition leads to a formula for the flow, in which there is a most material reduction in the number of constants for the determination of which we are obliged to have recourse to experiment.

There are various other investigations of Prof. Reynolds's which time would not allow me to enter into, and I therefore merely mention his investigation of the relation between rolling friction and the distortion produced by the rolling body on the surface on which it rests, that of the effect of the change of temperature with height above the surface of the ground on the audibility of sounds, and his explanation of the effect of lubrication as depending on the viscosity of the lubricant.

The Davy Medal has been awarded to Mr. Crookes for his investigations on the behaviour of substances under the influence of the electric discharge in a high vacuum.

Mr. Crookes's remarkable series of researches which conducted him to the invention of the radiometer led him to work with excessively high vacua. In connection with this he found that an electric discharge in such vacua is capable of exciting effects of phosphorescence apparently quite different in their origin from those produced in the ordinary way by such discharges. The latter are clearly referable to the action of the ethereal undulations which are propagated from the seat of the discharge. But the former involve in some way the effect of the actual transference of the molecules of ponderable matter. These phenomena in the hands of Mr. Crookes opened up a new means of discrimination between different bodies, and he has applied them as a test for the discrimination of groups of rare earths, not yet fully investigated. The test went hand in hand with processes of chemical separation. But here a great difficulty presented itself. So very closely allied in their chemical properties are the members of the groups, that it was only by an excessively tedious and laborious system of fractional precipitation that Mr. Crookes was able to effect a pretty fair separation. Even still, the separate existence of some members of the groups is more or less problematical. It is for these most painstaking researches that the medal has been awarded.

The existence, or apparent existence, of so many earths of such close chemical relationship led Mr. Crookes to speculate on the possibility that after all the molecules of what is deemed a chemical element may not be absolutely alike, as chemists have almost universally believed, but only very approximately so, and that what is deemed the molecular weight of the substance may really be that of the average of its molecules. Should such groups exist, it is conceivable that by processes of very delicate chemical separation they might be split up again into sub-groups, the molecules of which still more nearly match one another; so that according to this view the number of groups into which an element, or what is deemed such, might be split up, not, be it observed, by any dissociation, but merely by a sorting of the molecules which are very nearly alike, may be somewhat indefinite.

Chemists will not probably be disposed to give up the idea of the perfect similarity of the individual molecules of elementary bodies; but it is surely legitimate for one who has worked so assiduously at these difficult separations to suggest, merely as a matter for chemists to think about, a possible view of the nature of elements different from that to which they have been accustomed.

MOTIONS OF THE SOLAR SYSTEM.[1]

NO other hypothesis has been suggested which offers such direct and complete answers to most of the questions which relate to the origin, structure, and unity of the universe, as Newton's law of gravity. It is but natural, therefore, that the

[1] Abstract of an Address before the Section of Mathematics and Astronomy of the American Association for the Advancement of Science, at Cleveland, O., August 15–22, 1888, by Ormond Stone, Vice-President of the Section.

majority of the problems which arise in regard to the motions of the solar system should have their origin in an effort to confirm that law.

The first attempt to apply Newton's law to all the motions of the solar system was made by Laplace. When, however, Lindenau and Bouvard undertook to compute their tables of the motions of the planets, a complete revision of Laplace's theory was found necessary. So enormous is the labour involved, that there exists, besides those mentioned, only one other complete set of theories and tables of the motions of the principal planets—that of Leverrier. Leverrier's tables of the inner planets are now nearly thirty years old. His tables of the outer planets are much later, having employed his attention almost to the day of his death. His tables of Jupiter and Saturn were published in 1876, and those of Uranus and Neptune in the year following. Newcomb's tables of Neptune were published in 1865; those of Uranus, in 1874. Hill's theory of Jupiter and Saturn, which has for years occupied his attention, has at last been completed, and he is now engaged in preparing tables therefrom. These are intended to form a part of a complete series of tables of the principal planets now being prepared under the direction of Prof. Newcomb at Washington. Another such series is a'so being prepared by Prof. Gyldén at Stockholm.

The values of the coefficients of the terms of short period in the motions of the principal planets are now pretty well known; and the same might be said of the secular variations, were it not for the difference between theory and observation which exists in regard to the motion of the perihelion of Mercury, which was discovered by Leverrier, and has been confirmed by Newcomb, in a discussion of the observations of the transits of Mercury extending over a period of more than two centuries. The cause of this difference still remains unknown. The completion and comparison with observations of the new theory of the four inner planets, now being prepared under the direction of Prof. Newcomb, will be awaited with interest, with the hope that it may throw new light on this interesting subject.

The only recent original tables of the moon's motions are those of Hansen. These, like Leverrier's tables of the inner planets, are now more than thirty years old. These tables have been compared with observations, and agree fairly well with those made during the century preceding their publication, but not with those made before or since that time. The theoretical value of the acceleration of the moon's longitude is 6″; that found by Hansen from accounts of ancient total eclipses of the sun, 12″. Newcomb, however, considers these accounts as unreliable, and, limiting himself to the Ptolemaic eclipses of the "Almagest" and the Arabian eclipses of the "Table Hakémitc," obtains the value 8″·3, or, from the Arabian eclipses alone, 7″—a value but little greater than the theoretical value. Dr. Ginzel, from an extended examination of accounts of ancient and mediæval total eclipses of the sun, concludes that Hansen's value requires a change of only a little over 1″. His solution, however, in reality depends upon the ancient eclipses alone. The only other theory of the moon comparable with Hansen's is that of Delaunay. This theory, however, is limited to a determination of the inequalities in the motion of the moon due to the action of the sun, on the hypothesis that the orbit of the earth is a pure ellipse; and differs from that of Hansen in that the inequalities determined are not expressed numerically, but only symbolically in terms of arbitrary constants.

While the coefficients of the inequalities upon which Hansen's tables are based seem to be pretty well known, I am not aware that the tables themselves have been sufficiently checked, except by comparison with observations. Apparently the great desideratum now is a set of tables computed from Delaunay's theory in a completed form, or computed in some other way entirely independently of Hansen's. Until Hansen's tables are thus checked, it is questionable whether it can be safely said that the motion of the moon cannot be completely accounted for by the law of gravity.

The detection of the two satellites of Mars by Prof. Hall may be considered the most interesting recent achievement in pure discovery. It was not till the discovery of these satellites that a means was offered for the accurate determination of the mass of that planet. No satellites of Venus and Mercury have as yet been detected, and the values at present assumed for the masses of those planets are very uncertain.

In 1788, just one hundred years ago, Laplace published his theory of Jupiter's satellites. This theory is still the basis of the tables now in use. Souillart's analytical theory of these satellites appeared in 1881. The numerical theory was completed only within the last year, and the tables therefrom remain still to be formed.

Bessel made a careful investigation of the orbit of Titan; but the general theory of the Saturnian system which he commenced, he did not live to finish. Our knowledge of the motions of Saturn's satellites, with the exception of Titan, was very meagre until the erection of the great equatorial at Washington. A difficulty in the determination of a correct theory of the motions of Saturn's satellites is the fact that there are a number of cases of approximate commen-urability in the ratios of their mean motions. The most interesting case is that of Hyperion, whose mean motion is very nearly three-fourths that of Titan. In this case there is the additional difficulty that their distance from one another is only about one-seventh as great at conjunction as at opposition.

Our knowledge of the motions of the satellites of Uranus and Neptune depends almost entirely on the observations made at Washington. Quite accurate determinations of the masses of these two planets have been obtained. The large secular motion of the plane of Neptune's satellite, to which Marth has called attention, needs confirmation.

The number of the asteroids is so great that they have been the frequent subject of statistical investigation. The systematic grouping of the nodes and perihelia which exists was shown by Newcomb to be the effect of perturbation. Glauser finds that the grouping of the nodes on the ecliptic is a result of a nearly uniform distribution on the orbit of Jupiter. Prof. Newton had previously found that the mean plane of the asteroid orbits lies nearer to the plane of Jupiter's orbit than to the orbit plane of any individual asteroid. Eighty-five per cent. of the asteroids have mean motions greater than twice and less than three times that of Jupiter; and the mean motions of none approximate closely either of these, the two simplest ratios possible. The next simplest ratios lie beyond the limits of the zone; that is, there are no asteroids having mean motions nearly equal to or less than one and a half times that of Jupiter, and none nearly equal to or greater than four times that of Jupiter. The labour of determining the general perturbations and computing tables of an asteroid is as great as in the case of a major planet. It is no wonder, therefore, that tables have been prepared for scarce a dozen of these small bodies, and that these are already out of date.

Of well-known comets of short period, Encke's, which has the shortest period of any, possesses the greatest interest to the student of celestial motions, since it was from a discussion of the orbit of this comet that Encke detected evidence of the existence of a resisting medium which produces an acceleration in the comet's mean motion. This acceleration has been confirmed by the investigations of Von Asten and Backlund. The investigations of Oppolzer and Haerdtl indicate that there is an acceleration also in the mean motion of Winnecke's comet.

We have thus glanced briefly at the present condition of our knowledge of the motions of the principal bodies of the solar system. Only four cases have been found in which we cannot fully explain these motions, so far as known, by Newton's law of gravity. The unexplained discordances are the motion of the perihelion of Mercury, and the accelerations of the mean motions of the moon and the two periodic comets just named.

If we go beyond the solar system, we cannot tell whether Newton's law does or does not apply without modification to all parts of the universe. It is principally in the hope of answering this question that double-star observations are carried on; and, in the case of the many binary systems already detected, Newton's law is satisfied within the errors of observation. Nevertheless, this evidence is purely negative, and its value, it seems to me, not at all commensurate with the labour expended upon it, unless it be in the case of such objects as Sirius, whose observation may assist in the solution of the problem of irregular so-called proper motion. The angles subtended are in general so small that relatively large personal errors are unavoidable; so that, even though their motions be controlled by a law or laws of gravity widely different from that of Newton, it is not likely that such differences can be proved with any degree of certainty. It is rather to the study of the proper motions of the fixed stars and of the nebulæ, and then only after a lapse of hundreds and perhaps thousands of years, that we must look for a solution of this question.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—It is proposed to alter the system of papers in the second part of the Natural Sciences Tripos, which has lasted for many years, according to which questions in each subject are set in every paper. Formerly one question in each subject was so set; latterly at least two questions in each have been set. It is considered that under the present system candidates with an extensive knowledge of one subject may not have time to show such a competent knowledge of a second as is required to gain a first class. It is now proposed to set four separate papers in each of the eight subjects, and to combine them in groups of two subjects, so as to get the examination over in eight days. Probably this may remedy the evil complained of, which can only affect a minimum of candidates; but it will re-introduce the evil which the present system was intended to obviate—namely, it will give an opportunity for taking a number of subjects by means of cramming. It is also proposed to make the change next June, an altogether insufficient length of notice.

Prof. W. G. Adams, F.R.S., has been approved for the degree of D.Sc.

Mr. Francis Darwin, M.A., F.R.S., Reader in Botany, has been elected to a Fellowship at Christ's College.

Dr. Hill, Master of Downing College, has been appointed University Lecturer in Advanced Human Anatomy, and Mr. Walter Gardiner, Fellow of Clare College, University Lecturer in Botany, for five years in each case.

Dr. Guillemard has resigned the University Lectureship in Geography owing to ill-health, and a fresh election will take place in January, for the remainder of the term of five years, ending midsummer 1893. The stipend is £200 per annum. Candidates must send their names, with brief statements of their qualifications, and the methods they propose to adopt, to the Master of Caius College on or before January 8 next.

SCIENTIFIC SERIALS.

The Quarterly Journal of Microscopical Science for October 1888 contains the following:—On the structure of three new species of earthworms, with remarks on certain points in the morphology of the Oligochæta, by Frank E. Beddard (Plates xii. and xiii.).—This paper contains an anatomical description of *Acanthodrilus annectens*, n. sp., and *Deinodrilus benhami*, nov. gen. et. sp., from New Zealand, and *Typhæus gammii*, n. sp., from Darjeeling. Among the more important anatomical facts detailed, are the independence of the vasa deferentia and atria in Acanthodrilus; the independence of the single vas deferens and its atrium in Typhæus; the occurrence of six pairs of setæ in each (setigerous) somite of Deinodrilus; the completely double dorsal blood-vessel of Deinodrilus in a separate cœlomic space; and the presence in *Moniligaster barwelli* of an atrium consisting of a thick glandular covering of peritoneum, of a layer of muscular fibres, and finally of a single layer of columnar epithelium; the atrium being similar to that of Rhynchelmis.—On the development of the fat-bodies in *Rana temporaria*; a contribution to the history of the pronephros, by Arthur E. Giles (Plate xiv.). The fat-bodies in the frog are formed by a fatty degeneration, not of the anterior end of the genitalia, but of the pronephros or head kidney; it seems highly probable that the structure described by Balfour in the Ganoids and Teleostei as lymphatic tissue is the persistent but structurally and functionally modified pronephros.—On two new types of Actinaria, by Dr. G. Herbert Fowler (Plate xv.). In a bottle of corals, which had been collected from the reefs off Papieté during the expedition of H.M.S. *Challenger*, three small Actinaria were found, which would seem to differ markedly from all hitherto described types; so much so as to possibly necessitate the formation of a new tribe, of equal value with the Edwardsiæ, &c. The name proposed is *Thaumactis medusoides*, gen. sp. nn. The animal is flattened in shape, and almost medusiform; it appears to be free-swimming, for the aboral is like the oral ectoderm, and there is no trace of any attachment. Fourteen true tentacles surround the stomodæum, and peripherally to them are the pseudo-tentacles; the true tentacles with the stomodæum are drawn downwards and outwards into the cœlenteron; in the largest specimen twenty-one pairs of mesenteries, and in the smallest eleven pairs were present; no generative organs were met with. The second form was found attached to a piece of Millepore and is called *Phialactis neglecta*, gen. sp. nn. In this new genus the tentacles are replaced not by stomidia—slight elevations of the oral disk, surrounding the large opening which is homologous with the pore at the tip of some normal Actinarian tentacles—but by what the author calls "sphæridia," *i.e.* ampullate diverticula of the inter- or intra-mesenterial chambers, devoid of an opening to the exterior, and homologous, therefore, with the imperforate tentacles of many genera.—Morphological studies, ii. the development of the peripheral nervous system of Vertebrates; Part I, Elasmobranchii and Aves, by Dr. J. Beard (Plates xvi.–xxi.). This important memoir has appended to it a *résumé* of its chief results.

Revue d'Anthropologie, troisième série, tome iii. fasc. 6 (Paris, 1888.)—On the conversion of the cephalic index into a cranial index, by M. P. Topinard. This paper gives the author's reply to the objections raised by M. Houzé, of Brussels, against his method of determining comparative cephalic and cranial measurements. He explains the various methods employed by Broca and others, and points out the sources of error dependent upon the varying length of time in which skulls have been preserved owing to the gradual drying up of the cranial substance after prolonged preservation in our museums. Thus the craniometric determinations made under the latter conditions must be different from those obtainable immediately after death, or on removal from a damp humus.—Continuation of M. Boule's essays on the stratigraphic palæontology of man. The relations between the Pliocene and the Glacial formations of North America are here considered at length. In concluding his summary of the results yielded by the valuable labours of American palæontologists, M. Boule expresses his assent to the opinion advanced by Mr. Putnam, that recent discoveries afford conclusive evidence that a portion of North America from the Mississippi to the Atlantic was occupied by man contemporaneously with the mastodon and the mammoth, at a period when all the north of the continent was covered by vast glaciers. The closing part of the paper treats of the French classical beds at Chelles, Saint-Acheul, &c., from which date the earliest researches regarding fossil man in France.—On the concurrence in certain crania of divergent characteristics as exemplified in a series of Burmese skulls, by M. Hovelacque.—Kashgar and the passes of the Tian-shan Range, by Dr. Seeland. This is the first of a series of papers communicated by the doctor appointed by the Russian Government to institute proper measures for preventing the advance into the provinces of Semiretche and Ferganah of the severe epidemic of cholera, which had broken out in the Kashgar dominions in 1886. These provinces, which remained in a savage and uncultivated condition till they were brought under Russian dominion in 1862, are necessarily almost a *terra incognita*; and hence Dr. Seeland's narrative of his travels from Vierny to Ak-su in Kashgar, by way of Naryne, which compelled him to cross the colossal range of the Tian-shan range, is a valuable addition to our geographic knowledge of this portion of the Russo-Chinese frontier-lands, while his descriptions of their natural products, and his remarks on the habits and character of the Kirghis hordes, now being thrust back by the Russians, supply much information that is new to science.—Palæontology in Switzerland, by Dr. Victor Gross. This is a useful summary of the large and important mass of materials accumulated by recent Swiss palæontologists. After treating of the various periods of cave and lacustrine habitations, and of the later pile-dwellings, or *crannoges*, he considers at length the character and importance of the various finds belonging to the several stations. Of these, the Lakes of Bienne and Neuchâtel are remarkable, as having already yielded more than 19,500 complete bronze objects, of which fully three-fourths were of a decorative or domestic character, rings and pins numbering 4000. Important investigations are at present being carried out at the La Tène station, where the finds have hitherto been so exclusively connected with weapons of offence and defence as to lead to the inference that its pile constructions marked the site of some primitive fort. The search for lacustrine graves, successfully begun in 1876 is also being vigorously prosecuted.

Memoirs of the St. Petersburg Society of Naturalists, vol. xix.—*Geology and Mineralogy*:—*Dactylodus rossicus*, a new species of fish from the Moscow Coal-measures, by A. Inostrantseff.—The diabase deposits of Olonets, by F. Levinson-Lessing, being an elaborate work which contains a general geological and geographical description of the region, and a detailed

petrographical description of the rocks and their metamorphoses. A sketch-map and five plates of microscopical sections accompany the paper, which is well summed up in German.—Geological observations on the Yug River, by B. Polyenoff.—On the *Spaniodon barbotii* deposits of Crimea and the Caucasus, by N. Andrusoff (also summed up in German).—*Zoology and Physiology*:—Notes on the ichthyology of the basin of the Amur, by N. Warpachowski and S. Hertzenstein, being an elaborate description of forty species, and their connection with kindred species in neighbouring regions (diagnoses in Latin, and the whole summed up in German).—On the Vertebrate fauna of the Balkhash depression, by M. Nikolsky. The most interesting conclusions of the author as to the recent geological history of the Balkhash depression have already been mentioned in NATURE. Now we have a full description of the fauna (39 mammals, 226 birds, 21 reptiles, 3 amphibians, and 16 fishes), together with an elaborate inquiry into the connection of this fauna with those of the neighbouring regions.—The *Percarina* and *Benthophilus* of the Sea of Azoff, by J. Kuznetsoff.—The minutes of proceedings contain several papers of great interest—namely, on a journey to Dutch India, by A. Korotneff; on the ornithology of Caucasus, by K. Rossikoff; on the fossils of the Nijne-udinsk cave, by I. Tcherski; on a journey to Turkestan and Bukhara, by S. Lidsky, &c.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 22.—"On the Magnetization of Iron and other Magnetic Metals in very Strong Fields." By J. A. Ewing, B.Sc., F.R.S., Professor of Engineering in University College, Dundee, and William Low.

The large magnet of the Edinburgh University, kindly lent by Prof. Tait, was used throughout the experiments, and allowed the authors to effect a high concentration of the magnetic force by using bobbins, the necks of which had a cross-sectional area of (in some cases) only $\frac{1}{1600}$ of the cross-sectional area of the magnet cores. By this means the induction 𝔅 was raised to the following extreme values:—

	C.G.S.
In wrought iron	45,350
,, cast iron	31,760
,, Bessemer steel	39,880
,, Vickers's tool steel	35,820
,, Hadfield's manganese steel	14,790
,, nickel	21,070
,, cobalt	30,210

The induction was measured by means of a coil consisting of a single layer of very fine wire wound upon the central neck of the bobbin. Outside of this coil, at a definite distance from it, a second coil was wound, and the magnetic force was determined in the annular space between the two. In a paper communicated to the Manchester meeting of the British Association, the authors showed that if the force so measured could be proved to have the same value as the magnetic force within the metal neck itself, it would follow that the intensity of magnetism ℑ had begun to diminish under the action of excessively strong fields, in the manner which Maxwell's extension of the Weber-Ampère theory of molecular magnets anticipates. In the present paper the authors discuss at some length the question of how far the magnetic force within the metal is fairly measurable by the magnetic force in the ring of surrounding air, and they show that, with the form of cones originally used, the force within the metal must have been less than the force outside, by an amount probably sufficient to explain the apparent decrease of ℑ. The form of cone suited to give a uniform field of force with sensibly the same value in the metal neck and round it is investigated; and experiments are described in which the condition necessary for a uniform field was satisfied. The results of these experiments are conclusive in showing that no considerable change takes place in the value of ℑ (in wrought-iron) when the magnetic force is varied from about 2000 to 20,000 C.G.S. units. Throughout this range of force, the intensity of magnetism has a sensibly constant value of about 1700 C.G.S. units, which is to be accepted as the saturation value for wrought iron. The term saturation may be properly applied in speaking of the intensity of magnetism, but there appears to be no limit to the degree to which the magnetic induction may be raised.

The following are probable values of the intensity of magnetism when saturation is reached in the particular metals examined:—

	Saturation value of ℑ.
Wrought-iron	1700
Cast-iron	1240
Nickel (with 0·75 per cent. of iron)	515
Nickel (with 0·56 per cent. of iron)	400
Cobalt (with 1·66 per cent. of iron)	1300

Experiments were also made with specimens of Vickers's tool steel, and other crucible steels, Whitworth's fluid-compressed steel, Bessemer steel, Siemens steel, and Hadfield's manganese steel. This last material, which is noted for its extraordinary impermeability to magnetic induction, was found to have a constant permeability of about 1·4 throughout the range of forces applied to it—namely, from 2000 to nearly 10,000 C.G.S.

Physical Society, November 24.—Prof. Reinold, President, in the chair.—Captain Abney read a paper on the measurement of the luminosity of coloured surfaces, which was illustrated by experiments. In a communication to the Royal Society, General Festing and the author have described a method of comparing the intensity of the light of different parts of the spectrum, reflected by various pigments, with that reflected from white, and luminosity-curves have been constructed, the areas of which give comparative measures of the total luminosities. This method of comparison is accurate, but requires considerable time, and the author has devised a more rapid process. The coloured surface whose luminosity is to be compared with white is placed beside a white patch within a dark box. A direct beam of light passes through an aperture in the box, and a black rod casts a shadow on the coloured patch; another beam from the same source is reflected at an angle, and forms a shadow of the same rod on the white patch, the junction of the two shadows coinciding with that of the two surfaces to be compared. In the path of the direct beam is placed a rotating disk with angular openings, adjustable whilst rotating by a simple lever, and by this means the white patch can be made to appear too light and too dark in rapid succession. By gradually diminishing the range of oscillation of the lever, a position of equal luminosities can be found. The coloured surface is now replaced by a white one, and the adjustment again made; and from the angular apertures required in the two cases the relative luminosities are determined. Comparisons made in this way (the numbers relating to which are given in the paper) with emerald green, vermilion, French ultramarine, &c., gave results in close agreement with those deduced from the luminosity-curves obtained by the spectrum method. In reply to questions, Captain Abney said the spectrum method was the more accurate, and could be relied on to 1 per cent. The new method gave results within 2 per cent., showing that the eye is very sensitive to small changes of luminosity when such changes take place in rapid succession.—Prof. Rücker made a communication on the suppressed dimensions of physical quantities. In arranging a system of dimensional equations for thermal quantities, the question arises as to what are the dimensions of temperature. A degree of temperature, as measured by the ordinary arbitrary method of the mercurial thermometer, is not affected by changes in the units of length, mass, and time; but the numerical values of thermal quantities (J, for instance) depend on the scale of temperature adopted, say Centigrade or Fahrenheit. Two courses seem open, either of which renders a complete system of thermal dimensional equations possible: (1) temperature may be considered as a measure of energy, as in the kinetic theory of gases, and may be expressed as the energy of translation of a standard number of molecules (say that number contained in 1 cubic centimetre of air at standard pressure and temperature); or (2) temperature may be considered as a secondary fundamental unit. If the first be adopted, the dimensions of specific heat become M^{-1}, and the temperature of 0° C. is expressed by $1·5207 \times 10^6$ ergs. If a practical unit corresponding to $\frac{10^6}{18}$ ergs be adopted, this new unit of temperature will coincide with the Centigrade degree to about 1 part in 3000. The chief objection to such a definition of temperature is that the above relation between temperature and energy is not yet proved to hold for liquids and solids. If the second course be adopted, the dimensions of all thermal quantities may be expressed in terms of M, L, T, and θ, where θ is the unit of

temperature. Attention was directed to the difficulties students generally experience on finding the dimensions of the same electrical quantities to be different, according as they are expressed in electro-static or electro-magnetic measure, and that different quantities may have the same dimensions. The anomalies are shown to be due to the suppression of the dimensions of specific inductive capacity and permeability, each being called unity in air. By retaining K and μ in the dimensional equations, the author thinks that many difficulties will be avoided, the methods of transformation of units will be generalized, and the limits of our knowledge kept more clearly in view. Though the dimensions of K and μ cannot be determined, it is easily shown that those of the product $K^{\frac{1}{2}} \mu^{\frac{1}{2}}$ are $L^{-1} T$. Mr. Blakesley, in commenting on thermal units, strongly protested against the use of the word "*therm*" as a name for the unit of heat. If used at all, it should be reserved for the unit of temperature. Referring to the choice of fundamental units, he reminded the Society that the dimensions of quantities expressed in the electro-static or electro-magnetic systems become identical if the unit velocity be the velocity of light, and by choosing the unit of time as a suitable decimal part of a day, the relations between electrical and practical mechanical units could be simplified. Prof. Carey Foster, after discussing the effect of defining specific heat as a ratio, or as a quantity of heat as the dimensions of temperature, pointed out that, as quantity of heat = temperature × entropy, the dimensions of temperature would be determinate if those of entropy were found. Prof. S. P. Thompson considered that part of the difficulties of dimensional equations arose from the fact that no distinction was made between *scalar* and *vector* quantities. Thus the dimensions of work and moment of a force are given as ML^2T^{-2}, whereas the true representation for the latter would be $ML^2T^{-2}\sqrt{-1}$, because the line by which the force is multiplied is at right angles to the force. By similar considerations, Ampère's rule for the force between two parallel current elements can be derived from the magnetic equation $\frac{m \,.\, m'}{r^2} = f$, for, replacing m and m' by equivalent current elements, $i \,.\, ds$ and $i \,.\, ds'$, the equation becomes—

$$f = \frac{\sqrt{-1}\; i \,.\, ds \,.\, \sqrt{-1}\; i \,.\, ds'}{r^2}$$

$$= \frac{-i^2 ds \,.\, ds'}{r^2}.$$

Referring to the use of "therm," Dr. Thompson concurred with the remarks of Mr. Blakesley, and thought the word "calorie" answered all requirements. He also considered that thermal equations were greatly simplified by always expressing specific heat in ergs. Prof. Ayrton was of opinion that students experienced much greater difficulty in dealing with electrical units than with thermal ones, and thought part of this was due to the vague way in which some of the standard text-books treated the subject. With reference to the force exerted by quantities of electricity, Prof. Perry and himself had pointed out that specific inductive capacity must be taken into account, for, contrary to Faraday, they had found it to be different in different gases. In reply, Prof. Rücker said he often explained the identity of the dimensions of work and moment of a force, by considering moment as measured by the work done in rotating through unit angle, the dimensions of angle being zero as regards L, M, and T. He also pointed out that, in Bayne's "Thermodynamics," specific heats are always expressed in ergs. In thanking Prof. Rücker for his interesting paper, the President expressed his conviction that, by paying attention to the points considered, the difficulties arising from the two systems of units would be considerably diminished.

Chemical Society, November 15.—Mr. W. Crookes, F.R.S., in the chair.—The following papers were read:—The principles of thermo-chemistry, by Mr. S. U. Pickering. The author rejects the thermo-chemical principles enunciated by Thomsen, Naumann, and Berthelot, not only on special grounds, but on the more general ground that they depend on an impossible distinction between chemical and physical actions. A satisfactory explanation of all known thermo-chemical facts is derived from the recognition of the laws of dissociation and the hydrate theory of dissolution. Every act of combination must be accompanied by the evolution of heat, and in interactions where heat is absorbed this absorption must be due to the fact that, one or more of the agents being partially dissociated at the temperature of the interaction, the removal of one of the products of the dissociation necessitates a further decomposition of the agent. The heat evolved must also be a direct measure of the affinities saturated; and, of two possible interactions, that which evolves more heat must occur to the exclusion of the other. The cases of endothermic changes which present difficulties are those in which liquids and solids are concerned. The heat absorbed when many solids are dissolved in liquids cannot be explained by the fusion, but only by the volatilization of the solid. A mass of water contains some fundamental molecules possessing an energy of 10,000 cal. greater than the average molecular aggregates constituting the mass. These can therefore combine with the salt, and effect its volatilization with an evolution of heat, even if the heat of volatilization be nearly 10,000 cal.; other water aggregates then dissociate to supply the place of the free molecules thus removed from the sphere of action. From theoretical considerations the author arrives at the conclusion that Berthollet's theory as to the division of a base between two acids is correct, and argues that the facts observed are in accordance with these conclusions, and are entirely opposed to the existence of the so-called "avidity" or "affinity" constants advocated by Ostwald and others. In the discussion which followed the reading of the paper, Prof. Ramsay, F.R.S., said that he did not believe in the universal presence of complex molecules in liquids and solids, nor did he exclude the existence of such; the researches of Prof. Young and himself, he thought, conclusively established the absence of a complex molecular structure in such liquids as ethyl alcohol and ether, whilst, on the other hand, Henry's arguments testified to the complexity of the molecules of certain oxides, such as silica. With regard to water, which specially formed the subject of Mr. Pickering's remarks, it was to be noted that, whilst the vapour-density pointed to molecular simplicity, other arguments drawn from its behaviour when examined by Raoult's method were in favour of moderate molecular complexity. Prof. Armstrong, F.R.S., remarked that by taking into account the action of water, Mr. Pickering had advanced what appeared to be a rational explanation of many facts which hitherto had appeared paradoxical.—Note on the mixture of propyl alcohol and water, by Prof. Ramsay, F.R.S., and Prof. Young. The authors have determined the vapour-pressures of a mixture of propyl alcohol and water in the proportions $C_3H_8O : H_2O$, and like Konowalow, arrive at results adverse to the conclusion that a definite hydrate exists. Chancel found that this mixture distils over to the last drop at 87°·5 under 738 mm. pressure, but the authors find that the composition of the mixture of constant boiling-point varies with the pressure under which distillation takes place.—Note on the action of nitric acid on ammonium chloride, by Dr. F. E. Matthews. The principal gaseous product of the action of nitric acid on ammonium chloride in solution is nitrous oxide, and not nitrogen, as has been previously stated; the gas is mixed with small quantities of chlorine and oxychloride of nitrogen.—Ethylic cinnamyldiethacetate, by the same.—The isomeric sulphonic acids of β-naphthylamine, by Mr. A. G. Green. Three acids—the α-, β-, and γ-acids—are known to be formed when β-naphthylamine is sulphonated with ordinary sulphuric acid at 100°, but the author finds, as was to be expected, that the δ-acid is also present. The analogous behaviour of hydroxy- and amido-compounds makes it probable that β-naphthol on sulphonation gives four isomeric sulphonic acids, although two only have hitherto been isolated, and the author's experiments confirm this view, inasmuch as he has succeeded in isolating a third acid—corresponding to the β-naphthylamine-δ-sulphonic acid—from the product formed on sulphonating β-naphthol at 100°. In the discussion which followed, Prof. Armstrong, F.R.S., and Mr. Wynne pointed out that the formula adopted by Mr. Green as representing the constitution of the β-naphthylamine-α-sulphonic acid was at variance with the views put forward by Cleve and others, and could not be accepted; Mr. Green, in reply, defending his view that the α-acid is an ortho-compound, mainly on the ground that it and the corresponding β-naphtholsulphonic acid differed so greatly in properties from their isomerides.—The constitution of the dichloronaphthalenes, especially the $\alpha\beta$-compounds, by Prof. Armstrong, F.R.S., and Mr. W. P. Wynne. The three possible $\alpha\alpha$- and the two possible heteronucleal $\beta\beta$-dichloronaphthalenes are known, and formulæ have been ascribed to them which almost certainly are correct expressions of their constitutions. The authors point out that the four possible $\alpha\beta$-dichloronaphthalenes are also known, and draw attention to the somewhat discrepant statements on record relating to the so-

called θ-modification, melting at about 61°. The authors have found (Brit. Assoc. Report, 1887, p. 231) that under this designation two distinct dichloronaphthalenes have been regarded as one, and now bring forward evidence showing that one of these, melting at 61°·5, is a homonucleal, and the second, melting at 64, is a heteronucleal $\alpha\beta$-derivative. They confirm Cleve's view that the dichloronaphthalene, melting at 34°, is a homonucleal $\alpha\beta$-compound, the dichloronaphthalene melting at 48° being the remaining heteronucleal $\alpha\beta$-derivative. With regard to the constitution of the two homonucleal $\alpha\beta$-dichloronaphthalenes, the authors show that that melting at 61°·5 must be the *meta*-compound (that melting at 34° being, by exclusion, the ortho-derivative), since their experiments prove that so-called α-dichloronaphthalene, melting at 38°, and obtained by treating naphthalene tetrachloride with alcoholic potash, is a mixture of two homonucleal dichloronaphthalenes—namely, the $\alpha\beta$-derivative melting at 61°·5, and the $\alpha\alpha$-derivative melting at 68°. Sufficient data have not yet been obtained to determine the constitution of the heteronucleal $\alpha\beta$-dichloronaphthalenes.—Piazine derivatives, by Dr. A. T. Mason. A continuation of the author's work on a class of compounds formerly known as ketines, and more recently as pyrazines.

Anthropological Institute, November 27.—Francis Galton, F.R.S., President, in the chair.—The President exhibited a gold breastplate from an ancient Peruvian grave.—Mr. F. W. Rudler exhibited a collection of ethnological objects from the Jivaros of the Upper Amazons, and the Arawaks and the Acaways of the interior of British Guiana.—Mr. G. F. Lawrence exhibited two Palæolithic implements from the valley of the Thames, near Erith.—Mr. Osbert H. Howarth read a paper on the survival of corporal penance, and exhibited specimens of the "*disciplinas*," or scourges, which are still used, in public penance, in the village of Fenães d'Ajuda, a remote community on the north coast of St. Michael's, Azores.—The Secretary read a paper by the Rev. Benjamin Danks on marriage customs of the New Britain Group.

PARIS.

Academy of Sciences, December 3.—M. Daubrée in the chair.—Observations of the minor planets made with the great meridian instrument of the Paris Observatory during the first half of the year 1888, by M. Mouchez. The right ascension and polar distance, with correction of ephemerides, are tabulated for Diana, Danaë, Athamantis, Astrea, Parthenope, Flora, Sappho, Hebe, Cyrene, Germania, and five other minor planets.—On the satellites of Mars, by M. H. Poincaré. The paper deals with M. Dubois's recent hypothesis (*Comptes rendus*, August 20, 1888), that Phobos and Deimos were originally small planets, which a few years ago passed within the attraction of Mars. This hypothesis, which is based on the fact that the two satellites were never observed before 1877, is shown to be inadmissible by a consideration of the eccentricity of the orbit of Mars, and on other grounds. Although the eccentricity of Mars is about six times greater than that of the earth, it can be demonstrated that the elements of its moons cannot have perceptibly varied during the last hundred years.—On the preparation of the phosphorescent sulphides of calcium and strontium, by M. Edmond Becquerel. The author, who has lately resumed the study of these sulphides, now finds that some of the added substances, when employed alone, fail to produce any appreciable effect, and that the simultaneous presence of several is sometimes necessary for the preparation of strongly luminous bodies. The modifications depend not only on the nature of the mixed substances, but also on that of the phosphorescent sulphide itself.—On the invariants of differential equations, by M. E. Goursat. Since M. Halphen's researches on linear differential equations, M. Appell and others have extended the notion of invariants to differential equations of a more or less general form for certain special categories of transformations, without, however, determining in a general way the existence of these invariants. The determination is here effected by a demonstration based on Herr Lie's *Theorie der Transformationsgruppen*, (Leipzig, 1888).—On the dark waters of the equatorial regions, by MM. A. Muntz and V. Marcano. For the purpose of ascertaining the cause of the dark colour so characteristic of numerous affluents of the Amazons and Orinoco, the authors have analyzed some specimens from the upper course of the latter river. They conclude that the discoloration is due to the free humic acids held in solution, and derived from the decomposition of vegetable matter on a granite soil free from lime. The liquid is thus in some respects of the nature of bog-water, and the colour persists because, in the absence of lime, the phenomena of nitrification, and consequently the combustion of the organic matter, cannot take place, as shown by the complete absence of nitrates. The waters themselves are perfectly limpid, wholesome, and palatable, for although the discoloration is primarily due to their chemical composition, its intensity must be attributed to phenomena of reflection produced by the great depth of the liquid masses.—On the benzoic acetals of mannite and its homologues; decomposing action of benzoic aldehyde, by M. J. Meunier. The acetal of mannite is readily obtained by dissolving it in hydrochloric or sulphuric acid, adding a corresponding quantity of benzoic aldehyde and shaking; the mixture is rapidly transformed to acetal and solidifies. When a benzoic acetal, and doubtless others also, is completely freed from the excess of aldehyde, it resists the action of the acids as well as of the alkalies, and is not decomposed by prolonged boiling with acidulated water. In the presence of the aldehyde, on the contrary, decomposition takes place very rapidly by boiling, and all the more rapidly the greater the excess of aldehyde, even if the liquid be but slightly acidulated, containing, for instance, not more than 1 per cent. of sulphuric acid. Benzoic aldehyde thus influences the hydration of the acetal and the consecutive formation of mannite.—Action of the sulphide of carbon on clays; production of the oxysulphide of carbon, by M. Armand Gautier. During his researches on the mineralizing elements of thermal waters, the author has been led to attempt the synthesis of the oxysulphide of carbon by causing the vapours of the sulphide of carbon to act at red heat on the natural silicates, and especially on the argillaceous earths. These essays have been successful, and a method is here described which alone can furnish the oxysulphide of carbon, COS, in a pure state and in large quantities.—Transformation of terpilene into a menthene, by MM. G. Bouchardat and J. Lafont. By exposing terpine, $C_{20}H_{16},2H_2O_2$, for fifteen hours at 100° C. to twenty times its weight of aqueous hydriodic acid saturated at 0°, the authors have produced a dihydriodate of crystallized terpilene, $C_{20}H_{16},2HI$, identical with the dihydriodate of the essence of terebinthine. From their further researches they conclude that natural menthol should perhaps be grouped with the terpilene series.—On a spermaceti whale taken in the Azore waters, by Prince Albert of Monaco. Photographs are given of the head of a large spermaceti whale harpooned last summer in the neighbourhood of the Azores. It measured from the eye to the upper extremity of the mouth 1·90 metre, and from the under jaw to the lip 1·16 metre.—Papers are contributed by M. G. Saint-Remy on the brain of the spider family; and by M. A. Giard on *Peroderma cylindricum*, Heller, a parasite of the sardine.

BERLIN.

Physical Society, November 16.—Prof. du Bois-Reymond, President, in the chair.—Prof. von Bezold made a further communication on the thermo-dynamics of the atmosphere, in continuation of a statement made to the Society earlier in the year. After briefly recapitulating the processes which occur during the adiabatic expansion of a mass of air as it rises, he introduced into thermo-dynamic considerations a new idea, brought forward by Helmholtz, and found to be extremely convenient. The idea is that of "potential temperature," or in other words the absolute temperature assumed by a mass of air when it comes adiabatically under normal pressure. The speaker then propounded the following as a general law: "Whenever a mass of air changes its condition adiabatically, the potential temperature is never diminished, it is usually increased, and sometimes is unchanged." This law was proved from a number of examples. During the adiabatic alterations of pressure and volume in the currents of air as they rise and fall, the temperature should fall, on the average, about 1° C. for a height of 100 metres; as a matter of fact, the fall is really less than 1° C. This is due to the fact that under natural conditions the processes do not occur adiabatically, since near the earth's surface and above the level of the clouds warming and cooling influences are brought to bear on the air. In an anticyclone the powerful radiation from the earth leads to a cooling of the lower strata of air, and to this is due the fall of temperature observed at all stations which are situated on a height, a phenomenon which, according to the speaker, must also make its appearance at lower levels during maximal pressures of the air in winter and during the night. In cyclones the fall of temperature with increasing altitude similarly differs from its theoretical value, since warm air from the neighbouring anti-

cyclone becomes mixed with the colder air as it is rising, owing to the whirling motion: as a result of this, the formation of clouds must be most dense in the centre of the cyclone, and thinner towards its periphery. The latent heat liberated during the condensation accompanying cloud-formation is only obvious in the anticyclone, since it merely slows the rate of cooling in the rising current of air; on the other hand, the cold rain-drops as they fall cool the lower layers of air in a cyclone, so that as a result of the above a mixed convection of heat takes place from the cylone in the direction of the anticyclone. These thermo-dynamic considerations explain in general a large number of meteorological phenomena of which the speaker was only able to enumerate a few.—Dr. Budde made some remarks in connection with Janssen's communication to the last meeting of the British Association on the double spectrum of oxygen, of which one is proportional to the density of the gas, the other to the square of that density. He showed that on the supposition that one of the spectra is due to separate free molecules, the other to molecules which are impacting, the result must follow which Janssen has found experimentally.

Physiological Society, November 23.—Prof. du Bois-Reymond, President, in the chair.—Prof. Moebius spoke on the nests which are constructed by the marine stickleback (*Gasterosteus*). As early as 1829 the fact that this animal constructs a nest was described by an English observer. The speaker had had frequent opportunities of examining these nests in the Baltic, and found that they are constituted not only out of Fuci, Algæ, and other marine plants, but also out of the leaves of terrestrial plants which have fallen into the water, and even sometimes out of bits of wool. The male, who is constantly circling round the nest, knows how to find it again, even if it is lifted and lowered again into the water at a distance of five hundred paces from its first position. In an aquarium the speaker was able to observe that the male is continually spinning new fibres round the nest which proceed from out of the urinary bladder. The fibres are, as shown by chemical reactions, composed of mucin, which is not, however, secreted in the bladder, but by the kidneys. Sections through a kidney, treated with osmic acid and stained with hæmatoxylin, showed that only a few of the cells lining the uriniferous tubes are concerned in the elaboration of mucin, the others undergoing no such change. Out of the breeding-season none of these mucigenous cells are to be found in the kidneys, which are then less swollen. A case analogous to the above, of nests constructed of mucin derived from temporarily modified gland-cells, is found in Salangane, which produce the edible nests; these birds make use of a glutinous material for the construction of their nests, which is at times secreted by a gland, in this case the salivary gland. A comparative physiological-chemical analysis of these two secretions would be very interesting.—Prof. Munk gave an account of his researches on the physiology of the thyroid gland. It has long been known that in cases of excision of this gland in man the patients suffer from severe cachexia, to which they speedily succumb, with symptoms indicative of serious disease of the central nervous system; this fact has led to a long series of physiological researches, from which it appears that this small organ is of the greatest importance to life. It was assumed, in accordance with Schiff's views, either that it produces some substance which, passing into the blood, upsets the normal function of the central nervous system, or that it is concerned in the destruction of some injurious products of cerebral activity. Two years ago, as the speaker began his researches on the physiology of this gland, with a view to the discovery of the above remarkable substance, he observed solitary cases in which the dogs were only slightly ill, and then completely recovered, notwithstanding that the thyroid was completely extirpated; one dog showed no signs of any illness at all. Similarly in the literature of this subject, solitary cases are mentioned in which extirpation had no effect on the dog's health. The speaker had next changed his method of operating, merely isolating the gland from the surrounding structures, ligaturing the hilus, and replacing the isolated lobes in their original position. Some of the dogs with the gland thus isolated lived on in perfect health; in these the gland was found to have degenerated and become completely converted into connective-tissue. Others of the dogs became ill and died, and in these the gland had healed and recovered its vascular supply. From these experiments it followed that the thyroid is not an organ of absolute importance for life, inasmuch as animals can live in perfect health without it. It thus remained to determine what is the cause of the serious pathological condition and ultimate death which ensues when the thyroid is excised in man and other animals. A careful study of the symptoms showed that the normal functions of respiration, cardiac activity and nutrition, and of the nervous system, are upset, resulting in dyspnœa with powerful expirations, palpitation of the heart, relaxation of the arteries, derangement of the movements of deglutition, accompanied by vomiting, clonic and tonic cramps, resulting in epileptic attacks. It was further found that the dyspnœa and palpitation are primary symptoms, the cramps are secondary, and that death ensues during the latter. The dyspnœic attacks with the resultant conditions are undoubtedly due to the stimulation of nerves lying in the inflamed tissues after the extirpation of the gland, viz. the superior laryngeal, recurrent laryngeal, vagus, and sympathetic nerves. This is clearly shown by the fact that when the gland is simply isolated by a ligature the dogs live in good health, the gland at the same time degenerating, whereas in cases where the surrounding tissues inflame and lead to a renewed adhesion and vascularity of this organ the dogs became ill and died. The speaker was obliged to defer to the next meeting, owing to the lateness of the hour, the further description of his experiments, and of the conclusions to be drawn from them.

CONTENTS.

THURSDAY, DECEMBER 20, 1888.

THE "ENCYCLOPÆDIA BRITANNICA."

The Encyclopædia Britannica. Vol. XXIV. (Edinburgh: Adam and Charles Black, 1888.)

THE assertion attributed by the undergraduate to the Master of his College, "What I know not is not knowledge," might be made in sober earnest on behalf of the authors of the ninth edition of the "Encyclopædia Britannica" in their corporate capacity. Their task has been to compile a compendious summary of all that is best worth knowing; to set up a landmark which should indicate the point to which we have now attained, which should distinguish between the uncertain and the sure, between hypothesis and fact.

To affirm that they have in all respects succeeded would be to assume an omniscience from which even the boldest critic might shrink, but it is doing them bare justice to say that it is generally held by those most competent to judge that their work is worthy of themselves. Art and science, history and literature, everything from the cedar on Lebanon to the hyssop on the wall, are included, and article after article bears in the initials at its end the hall-mark which stamps it as a work of the highest authority.

The "Encyclopædia," therefore, is not a mere compilation. Many of the scientific articles, though avoiding the mistake of giving undue prominence to opinions specially associated with the authors' names, are evidently the product of minds capable of looking forward as well as around. They are not content with producing the stock evidence in favour of generally-accepted theories; they know their weak as well as their strong points. They tell the reader not only what has been done, but something of what there is yet to do.

As examples, and in choosing them we confine ourselves to writers who, though they shared in the work, have unhappily, and to the great loss of science, not lived to see its completion, we may refer first to Prof. Clerk Maxwell's contributions on molecular physics. His article on "Atom" has become famous. Under the head of "Capillary Attraction," he gave (in spite of a few slips which have been pointed out by Sir William Thomson) a fuller and more suggestive discussion of the theory of capillarity than is to be found in any other English treatise. Turning to other subjects, no higher authority on the microscope could have been found than the late Dr. Carpenter. The article on "Terrestrial Magnetism," by Prof. Balfour Stewart, is a masterly synopsis both of the present state of knowledge on this subject, and of the directions in which inquiry should be prosecuted.

It is not, however, our intention either to attempt to give a general outline of the scientific articles or to criticize those in the concluding volume. At the moment when the task is just completed, we would rather congratulate the editor, authors, and publishers, on a work in which they may fairly take an honest pride. The examples we have cited will suffice to prove to our readers that anyone who has access to a good public library may now find in the "Encyclopædia Britannica" a review of what is known on almost every scientific subject, together with references which are sufficient to direct him if he wishes to pursue it further for himself.

Of course we do not mean to assert that articles in the earlier volumes—some fourteen years old—are always up to date now. But in spite of this drawback it is no slight advantage to have a succinct account of the state of knowledge at a definite and not very distant epoch. No doubt, editor and publishers have gained much valuable experience during the progress of the work, and perhaps they will be able to pigeon-hole a scheme by which the tenth edition will be more rapidly issued. We live quickly now, and though fourteen years was at one time considered a not unreasonable probation for an expectant swain, it seems long to a modern subscriber who is looking for the colophon.

Now that the end has come, the work may be regarded by Englishmen—or rather, if our Scotch friends insist on regarding that word as excluding them, by Britons—with just pride. Its completion was celebrated, in accordance with our national custom, by a dinner, of which we give some account elsewhere. In the course of an admirable speech, which he then delivered, Mr. Adam Black referred to the circulation of the ninth, as compared with that of the eighth, edition. It appears that while five thousand copies of the eighth edition were sold, the circulation of the ninth has been ten times as great. No doubt this is due in part to the demand for the work in the United States, but we may also assume that there has been a largely increased demand in England. The fact deserves to be specially recorded as a very striking sign of the times. It affords remarkable proof that during the lifetime of a generation there has been a steady growth not only of general intelligence, but of an enlightened desire to seek for information on all important subjects at the best and most trustworthy sources.

In these days of specialism, it is well that those engaged in different pursuits should, in one task at all events, meet on common ground. In educational matters they are too often opponents, struggling for the prominence of their particular subjects, offering rival inducements to the ablest scholars. Round the table in Christ's College, last week, these differences disappeared. The old learning and the new shared a triumph together. Every man who could tell, better than they, something of real interest to his fellows was recognized as having a claim on their attention.

In the company of encyclopædists, however, though due attention is given to each, the amount due is measured with the most scrupulous care. If sometimes we despair of the future when we read the endless babble of the platform, we may take courage from the study of pages in which the description of fact and the expression of thought are reduced to their utmost concentration. There is still hope for a race which, though it is producing "Hansard," has produced also the ninth edition of the "Encyclopædia Britannica."

Memories of some of those who have been left by the way cast over such a meeting a sobering but not necessarily a saddening influence. The "Encyclopædia" is itself a proof that we are growing in knowledge which can be put to good account to make the lives of succeeding generations less toilsome and more elevated than they

would otherwise have been. Lives which have been spent in the effort to secure this knowledge have not been lived in vain. To aid in securing that the tenth edition of the "Encyclopædia Britannica" shall mark an advance in our mastery over Nature comparable with that which is chronicled in the ninth there are still those among us who "would even dare to die."

MEDIÆVAL RESEARCHES FROM EASTERN ASIATIC SOURCES.

Mediæval Researches from Eastern Asiatic Sources. Fragments towards the Knowledge of the Geography and History of Central and Western Asia from the Thirteenth to the Seventeenth Century. By E. Bretschneider, M.D. (London: Trübner and Co., 1888.)

FOR some years past, owing mainly to the labours of Colonel Yule, European students have been made acquainted with the travels of European explorers of the Middle Ages in Central Asia and China. In "Cathay and the Way Thither," published in 1866 by the Hakluyt Society, and especially in his monumental edition of 1875 of the travels of Marco Polo, Colonel Yule laid before the world a record of practically all that had been done by mediæval travellers from Europe in these regions. Dr. Bretschneider's work is of the same nature, inasmuch as it deals with explorations of the same period in the same regions, but with this exception—his travellers are Chinese and start from China, Colonel Yule's are European and start from Europe. The former goes to Chinese literature as his storehouse, the latter to European literature. Each is complementary to the other; and, indeed, Dr. Bretschneider acknowledges that it was Colonel Yule's works that led him to study and collect the materials supplied by Chinese literature regarding the mediæval history and geography of Central Asia. He found that such quotations from the works of Chinese travellers as had made their way to Europe were not always carefully or faithfully translated; and as his position of physician to the Russian Legation at Pekin gave him peculiar opportunities of study, and placed at his disposal the valuable and rare library of Chinese works collected over a long series of years, at the expense of the Russian Government, by the Russian Ecclesiastical Mission, he determined to investigate the subject at first hand for himself. The result was the publication, in the pages of the Transactions of the North China Branch of the Royal Asiatic Society between 1874 and 1876, of a series of papers dealing with Chinese knowledge of Central Asia, and Chinese travellers there from about 1200 to 1600. Three of these papers are collected in the volumes before us, and form, as it were, the backbone of the work, viz. "Notes on Chinese Mediæval Travellers to the West"; "Notices of the Mediæval Geography and History of Central and Western Asia"; and "Chinese Intercourse with the Countries of Central and Western Asia during the Fifteenth Century." The new edition is brought up to date by references to the results of recent researches and investigations of Russian and other travellers, and especially to the vast increase in our knowledge of these regions produced by the rapid extension of Russian territory in the direction of India and China.

Dr. Bretschneider tells us that Chinese literature contains very considerable accounts of the geography of Asia at different times, and of the nations which formerly inhabited that part of the ancient world. These are mostly to be found in the histories of the various dynasties which have successively ruled China. At the end of each of the twenty-four dynastic histories, a section is devoted to the foreign countries and nations which came in contact with the Chinese Empire. These were probably collected by Chinese envoys, or compiled from the reports of envoys or merchants coming from those countries. Another category is drawn up in the form of narratives of journeys undertaken by Chinese. They never travelled, it seems, for pleasure, or to enlarge their sphere of knowledge. We owe all their narratives of travel either to military expeditions, or official missions, or pilgrimages to places famed for their sanctity. The number of these reports is not inconsiderable; but the difficulty of searching them out is great, as they do not, as a rule, exist as separate publications, but lie concealed amongst collections of reprints; and many of them have been wholly lost, their existence at one time being known only from ancient catalogues, or quotations in books which have survived. The difficulties of elucidation also are very great, for even when translated they require a vast number of explanations. This will be understood when we mention that, besides prefaces, introductions, explanations in the text, &c., there are 1188 footnotes, some of them running over several pages, in these two volumes, containing altogether rather less than 700 pages.

The first paper, entitled "Notes on Chinese Mediæval Travellers to the West," is confined to the thirteenth century, "the period of the development and the zenith of the power of the Mongols in Asia," and the earliest journey recorded in it is the itinerary of Chinghiz Khan's army from Mongolia through Central Asia to Persia in 1219. This is followed by the record of the journey of an envoy of the Emperor of North China, sent in 1220 to Persia, and as far as the Hindu-Kush Mountains, to meet Chinghiz Khan. The third journey recorded is that of a monk, who travelled, by order of the great conqueror, from China to Samarkand. He left Shantung, in the extreme east of China in 1220, went by way of Pekin, crossed the eastern part of Mongolia, probably passed near the modern Uliassutai, traversed the Chinese Altai Mountains, near the present Urumtsi, and along the northern slope of the Thian-Shan Range to Lake Sairam, whence he descended into Ili, went through Tashkend, crossed the Syr-Daria into Samarkand, and thence went southwards to Balkh, and on to Cabul. He returned by the same route, except that he made a shorter cut across the Mongolian desert; and arrived at Pekin in 1224. Such a journey performed either way to-day would probably make the traveller the geographical hero of the year, and it is recorded that, when he entered Pekin on his return, "venerable old men, men and women, assembled from all sides, and accompanied the master (the traveller) with fragrant flowers, and bowing before him obstructed the road." The fourth traveller started from Mongolia, and going by Samarkand, went westward to the Elburz Range, and the country where the Mulahi or Assassins lived; and the fifth was a Mongol officer who wandered about Central Asia between 1260 and 1262. The records of these various journeys are full of the most

interesting details about the countries and people visited, told sometimes in a very quaint and amusing manner. The task of following their routes and identifying the places is appalling; but Dr. Bretschneider goes through it all, balancing theories, and comparing modern descriptions of the same places, with untiring patience and ever-ready learning.

The second paper is entitled "Notices of the Mediæval Geography and History of Central and Western Asia," drawn from Chinese and Mongol writings, and compared with the observations of Western authors in the Middle Ages. These also refer to the period of the Mongol supremacy in Asia, and are mainly drawn from records of warlike expeditions of the Mongols to the West in the first forty years of the thirteenth century. These are preceded by bibliographical notices of the Chinese, Mongol, Arabic, and other books used, an historical and ethnographical sketch of the Khitan, Karakhitai, and Uigur peoples, and, more interesting still, a discussion on the information of the Chinese at the same period about the Mohammedans.

The second volume opens with a curious specimen of mediæval cartography, a rude Mongol-Chinese map published in the first half of the fourteenth century; and about 140 pages of the volume are occupied with identifications of the places mentioned on the map. The last paper contains an account, also from Chinese sources, of their intercourse with the countries of Central and Western Asia during the fifteenth and sixteenth centuries. In this we are given the description by Chinese writers of over fifty tribes and peoples of the West, including Portuguese, Spaniards, and Dutch, as far as they were known at that period in China. A most interesting sketch of the early Jesuit missionaries in China is found under the head Italy, in which the struggles of the Jesuits to retain permission to reside at Pekin, the intrigues against them, and their success because of their scientific attainments, are all described. From this record it appears that in the sixteenth and beginning of the seventeenth century a considerable number of Jesuit fathers resided at Pekin, some of them holding office about the Emperor's Court, and that all died in China after a long residence. Ricci himself, the senior and predecessor of them all, lived in China twenty-eight years, Longobardi fifty-seven years, Emmanuel Diaz forty-nine years, and so on.

We cannot conscientiously say that the book is one for the general reader: its long notes, Chinese names in italics, and other outward and visible signs of learning will warn off all light-minded persons. But to the student of the geography and ethnology of Asia it is an indispensable aid, for it contains almost all that is at the disposal of those unacquainted with the Chinese language, of the observations and experience of Chinese travellers in Central Asia between the thirteenth and sixteenth centuries. We say "almost," because, since Dr. Bretschneider's papers were first published, Dr. Hirth has worked the same mine in his "China and the Roman Orient," published a few years ago, and the discussions which have arisen amongst Chinese scholars in consequence of this book have added much to our knowledge of Chinese literature relating to Central and Western Asia.

THE ORIGIN OF FLORAL STRUCTURES.

The Origin of Floral Structures. By the Rev. George Henslow, M.A., F.L.S. (London: Kegan Paul and Co., 1888.)

PROFESSOR HENSLOW'S book on the origin of floral structures tends to supply a want in botanical literature. It has the merit of being the first popular work which deals extensively with the morphology and development of the flower, and introduces to the English reader the work of Payer, Van Tieghem, and Baillon, besides further popularizing the exquisite researches of Darwin and Müller concerning the process of fertilization of plants.

The early chapters, which deal with the anatomy of the flower, though containing little original matter, present a good general view of floral anatomy and structure. The position of the various floral organs upon their axis having been deduced from the similar position and arrangement of leaves upon a vegetative shoot, we shortly come to the first of the author's main points, viz. the possibility of elucidating floral structures by an examination of the relative positions of the vascular bundles, or, as the author prefers to call them, "foliar cords." This idea is by no means new, and we venture to think that the author has not done sufficient justice to extant literature. It is, moreover, a great pity that the new expression cord has been substituted for the well-known vascular bundle, since there appears little or no need for it. In our opinion far too much stress is laid upon the position and distribution of the vascular bundles, as if the vascular bundles in every case determined the number and position of the various members of the flower and were not rather subservient to them, as certainly appears to be the case in many irregular flowers. In the discussion on the relative positions of the stamens and so-called petals of the Ranunculaceæ, Prof. Henslow has apparently not seen that Prantl has lately shown the so-called petals to be staminodes.

The second part of the work deals with the forms of flowers, and all the varied phenomena associated with fertilization. Prof. Henslow lays particular stress upon the theory that the shape of the flower as a whole, and also that of the various floral appendages, are definitely associated with, and bear relation to, the particular insects which fertilize them, and the further elaboration of this exceedingly probable hypothesis is the second main point to which he pays especial regard.

Nectaries—floral and extra-floral—he considers to have been brought into existence, equally with the rest of the floral appendages, through insect agency. Starting with a review of the cases of irritability and response to stimulus which so often occur in plant life, he further points out how frequently pathological growths, such as galls and the like, are formed by the irritation set up by insects, and argues that it is exceedingly probable that in the case of nectaries the perpetual irritation of particular localities by insects in search of the sweet juices which are present in the floral tissues, may have induced the formation of a definite glandular outgrowth, secreting nectar. This hypothesis is certainly ingenious, and even at the present time is not altogether without support. In the present state of the science it would, however, be premature to accept it without further and strong proof. Prof.

Henslow has no reference to Beccari's remarks which appeared in 1884 in the second volume of "Malesia" under the head of "Piante ospitatrice." In the preface to the descriptions of his exceedingly beautiful and well-known myrmecophilous plants, Beccari puts forward the very view taken by Prof. Henslow, both with regard to floral and extra-floral nectaries, so that Prof. Henslow has no need "to venture to go further" (*i.e.* than Beccari), and attribute the large honey-pits at the base of the leaf-stalk of *Acacia sphærocephala*—see p. 157—to the mechanical irritation of ants.

The book closes with some remarks on the origin of species and the origin of flowers. There is evidence that the author has not thoroughly acquainted himself with some of the literature to which he refers, and in certain instances important references are omitted altogether.

THE CORAL REEFS OF THE PENINSULA OF SINAI.

Die Korallenriffe der Sinaihalbinsel, geologische und biologische Beobachtungen. Von Johannes Walther, Dr. Phil., und Privat-docent an der Universität Jena. Des xix. Bandes der *Abhandlungen der Mathematisch-physischen Classe der Königl. Sächsischen Gesellschaft der Wissenschaften.* (Leipzig: bei S. Hirzel, 1888.)

MUCH has been written and said of late on the origin of coral reefs; yet the best authorities, when they have not theories of their own to uphold, are agreed in thinking that the matter is far from being finally settled. For this reason a thorough examination of all coral districts is much needed, and every work which adds to the general stock of knowledge on the subject deserves attention. The present memoir deals with the geology of the peninsula of Sinai, and the dependence of the coral reefs in the Gulfs of Suez and Akabah on the characters of the rocks forming the shores. Herr Walther has undertaken difficult and disagreeable, if not dangerous, journeys in the course of his research, and in point of thoroughness his observations leave little to be desired. Believing that a solution of the question in any given area can only be obtained by carefully studying the relations of the reefs to their basis, he has thoroughly examined the geological character of the western mountains of the peninsula, and gives in the first part of the book a full account of all that he observed. The results of his geological survey are most conveniently studied in the plate giving a series of sections through the peninsula. These show that south of Uâdi Firan there are two parallel lines of granite mountains, running north-west and south-east, and between them lies a basin filled in with sedimentary rocks. As far south as Gebêl Nakûs the granite forms the shore, and the author points out that in this region there is no fringing reef and no coral of any kind. Further south, where the sedimentary rocks form the sea-cliff, the fringing reef makes its appearance, sending out offsets from the shore from place to place, which form barrier reefs and even atolls. The shores of the Gulf of Akabah are granitic, and are devoid of coral reefs. Commenting on this, the author explains that the granite is rapidly weathered out, and that its surface thus constantly undergoing destruction does not afford a sufficiently firm basis for coral growth.

The coral reefs are divided into living reefs, sub-fossil reefs, and ancient reefs. The first are the fringing and barrier reefs or atolls actually being formed beneath the sea-level; the second are upheaved reefs, lying just above the sea-level, and consisting of coral heads cemented together; the third are infrequent, and consist of masses of dolomitic limestone, the structure of which betrays its coral origin, lying 230 metres above the sea. The thicknesses of these reefs were accurately determined, and were found to be, for the ancient reef, 15–17 metres; for the sub-fossil reef, 3–5 metres; and for the fringing reef, 3 metres. These facts are by far the most important part of the author's work; they prove that considerable changes of level have taken place since the coral reefs were first formed, and that these changes have been in the direction of elevation. Thus another instance is added to the many now accumulating of barrier reefs and atolls being formed in an area of elevation. The slight thickness of the reefs also deserves attention. At the end of the book the author speaks of a reflux of the sea having occurred rather than an upheaval of the land. As he does not explain what he means by a reflux of the sea, his statements are rather puzzling. Does he hold the view that considerable changes of sea-level have occurred as consequences of glaciation at either pole? In any case, the phenomenon which he seeks to account for by an alternating level of the sea, viz. the existence of a dead reef below the sea-level and beneath the living fringing-reef at Râs Muhámmed, requires for its explanation nothing more than a period of subsidence following on a period of elevation; and several of the geological facts seem to point to a recent though slight subsidence at the southern end of the peninsula.

The author adds nothing to our knowledge of the biological conditions and the composition of coral reefs. His accounts of the living coral and its mode of growth, of the filling up of the interstices of dead coral blocks with detritus, and the formation of oolitic granules, are familiar to all visitors to coral lands, and have been fully described by previous authors. Although an unnecessary amount of space is devoted to the description of these well-known phenomena, the whole work demands the attention of geologists and of students of coral formations. The numerous plates and woodcuts render the text light and easily comprehensible, and the map showing the condition of the coral reefs at different geological periods is of especial interest.

G. C. B.

OUR BOOK SHELF.

The Book of the Lantern. By T. C. Hepworth, F.C.S. (London: Wyman and Sons, 1888).

THE lantern has of late years become such an important aid to almost every branch of education, even in theological and political matters, that no apology is needed for the publication of a thoroughly practical treatise on everything connected with it. As a former lecturer at the Royal Polytechnic Institution, and present lecturer at the Birkbeck, Mr. Hepworth has gained the practical experience the benefits of which he now places at the disposal of others.

After brief reference to the history of the lantern, the optical arrangements are considered, and these are

followed by instructions for the preparation and storage of oxygen, which is now so commonly employed in conjunction with hydrogen, or ordinary gas, for illuminating purposes. The preparation of slides of every description, micro-photography, and the process of making lantern enlargements, are all fully considered. One chapter is also devoted to the description of a few simple scientific experiments, which can be easily performed whilst projected on the screen. Finally, a few valuable hints are given to aspiring lecturers or entertainers who wish to avail themselves of the powers of the lantern.

The necessary references to firms which supply particular appliances have been made without any partiality. The addresses of such firms might have been given with advantage.

The book is full of practical hints from beginning to end. It is very readable, and we can confidently recommend it to all who are concerned with lantern matters in any shape or form.

Chemical Problems. By J. P. Grabfield, Ph.D., and P. S. Burns, B.S. (Boston: D. C. Heath and Co., 1888).

THE systematic part of this book occupies the first forty-six pages, the remaining forty pages containing reprints of examination papers. The first part contains general information as to chemical calculations and such matters, with some problems worked out which are likely to be of service to the elementary student; but there are a few points that appear open to improvement. The word reaction is used in its ordinary sense, and also to indicate an equation without the figures that indicate the numbers of the several molecules; to adopt the words of the authors, an equation is a balanced reaction. This appears to be a needless perversion of the meaning of a useful word. The student is told to "balance the reaction" "by repeated trials" of numbers, a method that is certainly very common, but entirely unscientific and unnecessary—in short, a method of cramming, and not a method of teaching. At p. 12 we read, without qualification, "that the weights of all gases are to each other as their molecular weights": it would be very inconvenient to the commercial maker of gases if the weights of his productions were so restricted. At p. 5 the word weight is used in yet another sense: "If we divide the *weight* of any element in the molecule, multiplied by 100, by the per cent. of that element, we will have the molecular weight." This looseness of language would, we fear, be confusing to most students and to many teachers. The volume will be chiefly useful to those who are preparing for the examinations indicated in the second part.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Recent Eruption at Vulcano.

IN a letter recently received here from Mr. Narlian at Lipari, that gentleman mentions some interesting facts relating to the recent eruption of Vulcano. Amongst others, he says that some weeks since some fishermen crossing between Sicily and Vulcano "found themselves in a boiling sea, the water bubbling up," "pieces of pumice coming up through the water." It appears also that the cable between Capo Milazzo and Lipari has been broken at about the same place, which is marked by "large rocks." He then says he has been unable to examine any of the pieces of pumice said to have come from the bottom of the sea.

Whether we have evidence here of a submarine eruption or of a fumarole it is difficult to decide, but further information we must hope will be forthcoming. It is possible that it is simply a submarine fumarole or spring, similar to the Sorgente Le Caldaje, which is met with in the sea at a point forming a triangle with the islets of Lisca Bianca and Bottaro between Lipari and Stromboli.

The following is the latest information in regard to the eruption of Vulcano (the letter is dated Lipari, December 12):—

"Some weeks since, the crater itself showed signs of diminishing activity. The eruptions are often at intervals of hours from each other, and never of such violence. Some days ago, a gentleman, Mr. Salino, says he had gone to the top of the mountain and seen the interior. This gentleman assured me that two-thirds of the old crater is filled up (he had visited the place eighteen years ago!); there was an opening of about 100 metres in diameter in the north-east side of the crater. No lava was seen."

From this it appears that the eruption is diminishing; that probably this filling up of the crater is due to the construction of a cone of eruption, or that it is being choked by the materials ejected from the new opening in the north-east side. Of course without examining the locality one can only conjecture what has really taken place. H. J. JOHNSTON-LAVIS.

Naples, December 15.

Natural Selection and the Origin of Species.

FOR the third time Mr. Thiselton Dyer announces that his judgment is opposed to the theory of physiological selection. But this is not the point that I am debating. I am not discussing the merits of my theory, or endeavouring to influence the opinion of a critic who, after having shown that he had not read my answer to the criticisms which he triumphantly reproduced as never having been answered, now tells us that he has "devoted a good deal of time to the study of" my "views." From the first I have restricted myself to meeting his specific allegations. Still restricting myself to the same ground, I find that there are but two points in his last letter which it is necessary for me to consider.

First, touching the inutility of some, as distinguished from the alleged utility of all, specific characters, Mr. Thiselton Dyer expresses impatience with me for putting what he regards as a "strained interpretation" on Mr. Darwin's writings.[1] Now, of all things in the world, this is exactly what I should most wish to avoid. But, rightly or wrongly, I am profoundly convinced that such strained interpretation as there is, here lies on the other side. Over and over again—and more and more emphatically the later the editions of his works—Mr. Darwin insists that he does not regard natural selection as the only agent which has been concerned in the origination of species, and therefore concludes—to quote only one additional passage from among many to the same effect: "No doubt the definite action of changed conditions, and the various causes of modification, lately specified, have all produced an effect, probably a great effect, independently of any advantage thus gained" ("Origin," p. 160). Moreover, towards the close of the last edition, he complains most bitterly of "steady misrepresentation" with regard to this very point (p. 421)—a complaint all the more forcible from its presenting the only note of bitterness that is to be met with through the whole range of his writings. Now, since his death, this "steady misrepresentation" has continued, until the post-Darwinian school have come to designate by the term "pure Darwinism" the very doctrine which he here so vehemently repudiates.

This doctrine of utility as universal was very clearly enunciated in his own life-time by Mr. Wallace, as "a necessary deduction from the theory of natural selection" ("Contributions," &c., p. 47), but, as just remarked, he expressly renounced it in his section headed "Utilitarian Doctrine, how far true." Therefore I say that, quite apart from all questions of biological theory, or merely as a matter of historical fact, any charge of "strained interpretation" must here lie at the door of those who seek to attribute to Mr. Darwin the opinions which have always been held by Mr. Wallace, and which have now been adopted by the school of Prof Weismann. Moreover, not only is there no sense or reason in speaking of the passages in

[1] He says: "What, however, I view with less patience than his unsustained generalizations, is his persistent attempt to place them on the shoulders of the Darwinian theory." Elsewhere, however, the crown and front of his charge is that I have sought to shrivel up the Darwinian theory to very small dimensions—nay, that I have roundly denied it altogether, if my words have any meaning. How these contradictory criticisms are to be reconciled I must leave their author to explain.

question as "admissions wrung from a hostile witness," or as due to Mr. Darwin "admitting the possibility of explanations to which he really, however, did not attach much importance;" but by thus endeavouring to belittle his judgment on these points, the post-Darwinians are merely showing the weakness of their own. These passages are due to Mr. Darwin having clearly perceived that the doctrine of Mr. Wallace was neither sound in logic nor true in fact. Not sound in logic, because it does not follow as a "necessary deduction from the theory of natural selection," that all specific characters must be adaptive—it being sufficient for the theory if only some such characters are adaptive in each case, as Mr. Huxley has recently shown; not true in fact, because any number of cases (such as those given by Mr. Mivart) can be quoted to the contrary. Therefore, as I said two years ago in the *Nineteenth Century*, those who seek to encumber the theory with this illogical deduction are merely giving occasion to the enemy; it is a gratuitous dogma, standing like the feet of clay in a figure of iron.[1]

But to pass on to the second point. In my last letter I challenged Mr. Dyer to justify his statements that I had roundly denied the agency of natural selection as "the mechanical means by which evolution has been brought about," and that the theory of physiological selection "shrivels up the part played by natural selection to very small dimensions." In answer, he quotes a passage from my paper, and agrees with me that what it says is substantially the same as what the *Times* said. But he still fails to see that this is totally different from what he himself said. In other words, unlike the *Times*, he does not perceive the validity of my distinction between natural selection as a theory of species and as a theory of adaptations. Physiological selection, he thinks, shrivels up natural selection, because, if a true principle in Nature, it must play an important part in the origination of species, and, in whatever measure it does this, it must in a corresponding measure detract from the importance of natural selection. Having at last got him to show that this is his way of regarding the matter, I must first of all repeat that natural selection, besides being a theory of the origin of species, is also something very much more: it is a theory of the cumulative development of adaptations, wherever these occur. In fact, it is, as I have before said, *primarily* a theory of adaptations in all cases, and only becomes *incidentally* a theory of species in those cases where the adaptations happen to be of merely specific value. It is now perfectly evident that Mr. Dyer fails to perceive this distinction; hence his misunderstanding of my views, and hence also the present correspondence. He regards the "origin of species" as synonymous with, and therefore as covering the whole field of, "organic evolution": therefore he accuses me of roundly denying natural selection as "the mechanical means by which that evolution has been brought about," on the ground that I have suggested a supplementary theory of the origin of species. Such being manifestly the impression under which he has read my paper, it is no wonder that in the process he has been, as he says, "completely befogged." I will now endeavour to clarify the matter by explaining at length what I had supposed the readers of my paper would have recognized for themselves.

It is quite true that the evolution of adaptations depends upon the evolution of species, the serial succession of which, in any given line of descent, is the necessary means (through the struggle for existence) to the gradual development of adaptations in that line. But it is of no consequence how many "indifferent" characters these successive species display, provided that they also display, in ever-improving degrees, the particular adaptive characters which are in course of evolution. A bird's wing, for example, is an adaptive structure which cannot be evolved as a merely specific character; it requires to be slowly built up through the lives of an enormous number of successive species, which ramify into genera, families, &c., as the process goes on. Now, throughout this process it is a matter of no consequence how many *other* features of a *non-adaptive* kind arise among all these innumerable species: it is enough, as regards the evolution of a wing, that at each stage of the process *some* of the species should present slight improvements on their predecessors in respect of this adaptive structure. Physiological selection, sexual selection, geographical isolation, "changed conditions" as to climate, &c., or any other "factor," may all the while have been originating any number of *species*, without reference to their wings, though, at the same time, natural selection was continuously promoting the development of wings in *genera*, *families*, and *orders*. In short, species are like leaves, successive and transient crops of which are necessary to the gradual building up of adaptations, while these, like the woody and permanent branches, grow continuously in importance and efficiency through all the tree of life. Now, it is the office of natural selection to see to the growth of these permanent branches: physiological selection has to do only with the deciduous leaves. Hence, although natural selection has likewise an immensely large share in the origination of species (*i.e.* has to do with all species which are distinguished by adaptive characters *peculiar to themselves*), this, in my view, is really much the least important part of its work. Not as discovering *an* agent in the differentiation of species, but as revealing *the* agent in the genesis of adaptations, do I regard Mr. Darwin's theory as the greatest generalization in the history of science. If this view of the matter betrays on my part, as Mr. Dyer says, a fundamental misunderstanding of that theory, I shall be greatly obliged to him for showing me wherein the misunderstanding consists. In the event of his doing so, I will cheerfully renounce the inquiry on which I am engaged, for then, no doubt, my theory would be found in opposition to—and not, as I suppose, in co-operation with—the theory of natural selection. On the other hand, should he fail to meet this request, I shall have "reluctantly to arrive at the conclusion" that the "fundamental misunderstanding" in this matter, like the "strained interpretation" previously considered, lies the other way.

It will now, I trust, be sufficiently evident why I differ *toto cœlo* from Mr. Dyer where he concludes that the theory of physiological selection shrivels up the theory of natural selection. In point of fact, the former theory stands to the latter in precisely the same relation as does the theory of sexual selection. In both these supplementary theories, it is the origin of species that is concerned, and so concerned with reference to characters that are non-adaptive. The cases being thus precisely parallel, I should like to know whether my present critic regards one of Mr. Darwin's own theories as shrivelling up the other.[1] Assuredly, Mr. Darwin himself did not think so, because he clearly perceived that the "origin of species" constituted but a small part of the whole field of "organic evolution." It is true that he entitled his work "The Origin of Species by means of Natural Selection," and therefore in my paper I was careful to point out that, "if it appeared somewhat presumptuous to have insinuated that Mr. Darwin's great work on the 'origin of species' has been mis-named," there were passages in the work itself which fully justified me in my definition of his theory. My critic now quotes this explanation as justifying his statement that I intended to deny the agency of natural selection altogether! I do not quite know how to meet an opponent who resorts to such strange devices; but I may at any rate assure him that in my opinion no more appropriate title could have been chosen by Mr. Darwin for his great work than the one which he did choose; and if I spoke of that work as having been mis-named, I thought I had made it clear enough that I was "strictly speaking," or speaking to a point of logical definition. Moreover, at the time when the work in question appeared, the problem as to the origin of species was, as its author says, "the mystery of mysteries." But

[1] In connection with this point I have to express regret for a verbal error which Mr. Dyer has already pointed out in my last letter. But, from what he says of Prof. Nägeli's essay, it appears to me that he cannot have read it. At any rate, it is in no way confined to "the inutility of family characters," and in considering it Mr. Darwin supplies more than two pages of instances to illustrate his argument therewith, ending with the general conclusion:—"We thus see that with plants many morphological changes may be attributed to the laws of growth, and the interaction of parts, independently of natural selection." To ignore all such passages, or to regard them as admissions," is assuredly—once more to quote my critic's words against himself—"entirely to misapprehend their significance, or the spirit in which they were made"

[1] In this connection it is interesting to note that Mr. Wallace has always been the principal opponent of the theory of sexual selection, as he now is of the theory of physiological selection. Moreover, the reason of his opposition in both cases is that he thinks such subordinate theories of the origin of species must fail to find a *locus standi* in the presence of the greater theory of natural selection: the latter, in his view, must necessarily "shrivel up" the former. Now, his arguments against sexual selection are incomparably stronger than those which he has advanced against physiological selection (compare "Tropical Nature," pp. 192–211, with the *Fortnightly Review* for September 1886, and the *Nineteenth Century* for January 1887); yet they failed to influence the judgment of Mr. Darwin, whose very last words to science—read a few hours before his death to a meeting of the Zoological Society—were: "I may perhaps be here permitted to say that, after having carefully weighed, to the best of my ability, the various arguments which have been advanced against the principle of sexual selection, I remain firmly convinced of its truth."

now that we have all come to recognize species as nothing more than pronounced varieties, it appears to me a curiously interesting example of the "survival" of traditional modes of thought, that so many systematists still continue to regard the value of Mr. Darwin's theory to consist in what is really its least important function. The result has been clearly displayed in the present correspondence:—

There's such divinity doth hedge a species,
That science can but peep to what it would.

London, December 8. GEORGE J. ROMANES.

Engineers *versus* "Professors and College Men."

PROF. TAIT in his recent letter says that the only meaning the expression $\frac{Mv^2}{2g}$ conveys to his mind is the product of a mass by a length. But how does he measure his mass and his length? Is the mass to be measured in pounds or kilogrammes, or to be measured in units of g pounds or g kilogrammes? And is the unit of length the foot, or the metre or centimetre? so that g is variously 32, 9·81, or 981.

These are the points which are slurred over by "Professors and College men," but are of fundamental importance to practical engineers, who dare not trust to a formula till they have verified it numerically.

Let me conclude by giving Prof. Tait a question, selected from College text-books:—

"What is the meaning of $\frac{Mv^2}{2g}$ when the unit of area is one-tenth of an acre, the numerical value of g is 2, and the unit of weight is the weight of unit volume of the standard substance (the substance of which the specific gravity is unity)?"

I think he would be amused by the variety of answers he would receive, although the answers might individually be all correct.

December 17. A. G. GREENHILL.

Mr. Dodgson on Parallels.

MR. DODGSON has written to me thanking me heartily for my "interesting and helpful review" of his "New Theory of Parallels." He admits his slip in the corollary on p. 11, and supposes, as I had myself thought, he took ADC to be the triangle required instead of ABF. "But there is *one* criticism of yours which, if true, would vitiate the whole treatise. May I ask you to reconsider the point, and, should you see reason so to do, to notify to the readers of NATURE that you withdraw it? You say that, in Props. viii., xi., I tacitly assume that the 'amounts' of triangles are either *all* greater than two right angles, or else *all* less. . . . Such an assumption would indeed be monstrous." I willingly accede to Mr. Dodgson's request, as the following form of his argument, supplied in his letter to me, does away with my difficulty. "Either (α) there is a triangle whose 'amount' = two right angles, or (β) there is none. If (β) be true, then either (β1) *all* triangles have *greater* 'amounts,' or (β2) *all* have *less* amounts, or (β3) some have *greater* amounts and all others *less*. Now (β1) is proved impossible, in Prop. viii.; (β2) is proved impossible in Prop. xi.; (β3) may easily be proved impossible, by means of Prop. vii. Hence (β) is impossible. Hence (α) is true." It will be well, if, in a future edition, the missing link of (β3) be supplied. One other point puzzles Mr. Dodgson. It is my remark on Prop. vi.: "How are the figures to be constructed if $n>2$?" Mr. Dodgson says: "It surely does not need pointing out that the operation of bisecting an angle may be repeated *ad libitum*." Certainly not. But what I meant was the effect of these bisections upon the resultant chords. The figures to the proposition are incorrectly drawn: in the one figure BD, DC, and in the other BE, ED, DF, FC are *not drawn* greater than the radius, and my point was not the bisections but the enlargement of the figure: thus if $n = 3$, we should have eight triangles, vertices at the centre A, with the sum of their angles greater than 480°. My apology for thus trespassing upon valuable space is my desire to meet Mr. Dodgson's natural wish, and by pointing out what I thought were faults in his "interesting" *brochure* to enable him to make it more perfect in after editions. R. TUCKER.

University College School.

The *Porcupine* Echinoidea.

THE researches lately published by the Drs. Sarasin upon the anatomy of the Echinothuridæ, render a careful reconsideration of the types of Asthenosoma collected by the late Sir Wyville Thomson, during the voyage of H.M.S *Porcupine*, absolutely necessary in my opinion. The species were described in the Philosophical Transactions for 1874. I shall be much obliged if information can be sent me regarding the whereabouts of the specimens which were figured by Wild, *i.e.* the type-specimens of *Calveria* (*Asthenosoma*) *hystrix*, Wy. Th.; *C.* (*Asthenosoma*) *fenestrata*, Wy. Th.; and *Phormosoma placenta*, Wy. Th.

P. MARTIN DUNCAN.

Angry Birds.

IN reference to the notice of a fierce pheasant mentioned by Mr. Maw in the number of NATURE for December 13, I would refer him to my "Observations in Natural History" (p. 172), in which I have spoken of a daring cock pheasant, which I saw myself, while walking in the grounds of a friend in Cambridgeshire. This bird was in the habit of attacking any persons that approached near the spot where he was. Some woodcutters at work on the grounds had to protect their legs with strong leather gaiters. L. BLOMEFIELD.

Bath, December 18.

TWO years ago, whilst walking across a fallow field here, I heard a fluttering of wings, and received a violent blow on the back of the neck from a partridge: before I could recover myself she struck the back of my head and knocked my hat off. Although I had a heavy stick, I could not drive off the bird, who made a loud noise, and now attacked me in front. As I walked rapidly off, the bird followed and struck at me many times, attacking my head and shoulders with the greatest determination and violence. W. G. SMITH.

Dunstable.

PRESENTATION OF A PORTRAIT OF PROFESSOR A. W. WILLIAMSON, F.R.S., TO UNIVERSITY COLLEGE.

ON Wednesday (the 12th inst.) a portrait of Prof. A.W. Williamson, late Professor of Chemistry to University College, London, was presented to the College by Sir Henry E. Roscoe, M.P., F.R.S., on behalf of the committee of subscribers. The portrait is painted in oil by the Hon. John Collier. The presentation took place in one of the lecture-rooms, the chair being taken by the President of the College (Mr. John Erichsen, F.R.S.); and amongst those present were Sir F. A. Abel, Prof. Bonney, Prof. H. Morley, Dr. J. H. Gladstone, Prof. George Carey Foster, Dr. Atkinson, Prof. Ramsay, Prof. Thorpe, Prof. Marks, Prof. Russell Reynolds, and other Professors, and a large number of the past and present students of the College.

Dr. W. J. Russell, on behalf of the Committee, for whom he had acted as Treasurer, said that judging from the subscription list there was a large number of the former colleagues of Prof. Williamson who had subscribed to this portrait; and it would no doubt be very pleasant to him to know that members of all the Chemical Societies in England had liberally subscribed towards the portrait; and further, that many of the subscribers had not satisfied themselves by sending formal contributions, but had written to him (Dr. Russell) expressing their great esteem and regard for Dr. Williamson. The subscriptions did not come only from various parts of Great Britain, but from France, Germany, Switzerland, Italy, Russia, and even so far afield as the United States, Jamaica, India, and Japan. He thought this was all that it was necessary for him to say in order to indicate the high value which the subscribers attached to the great scientific attainments and labours of Dr. Williamson, whose intimate friends and old pupils, those who knew him best, now came forward to pay him this mark of their esteem and regard.

Sir Henry Roscoe, M.P., said:—I consider it, sir, a privilege that, as an old pupil and an attached friend of Dr. Williamson, I should have been chosen, on this occasion, to present his portrait—which I think you will

all consider as a life-like one—by Collier, to the College in which he laboured so faithfully and so successfully for nearly forty years. The first appointment of Dr. Williamson dates, as you, sir, are aware, from the year 1848, when, following Fownes, he was, as Professor of Practical Chemistry, placed in charge of the first teaching scientific laboratory established in England, and in a few years afterwards, on the resignation of Graham, he assumed the responsibilities of the two Chairs of Chemistry. A favourite pupil of Liebig's, Williamson had at Giessen imbibed the scientific spirit of that great master, and had, at the early age of nineteen, published his first original investigation. Afterwards carrying on his studies in Paris, and becoming intimate with Laurent and Gerhardt, he brought to London the best traditions of the French as well as of the German schools of chemistry, uniting in his person the attributes of both. Entering upon his duties in this College with the enthusiasm for his science characteristic of his nature, was it to be wondered at that he should have imparted to the young men who were fortunate enough to come under his influence some sparks of that fire which burnt so brightly in his own breast? I well remember the vivid interest, the keen appreciation, with which all those who studied in the Birkbeck Laboratory at that now distant time followed step by step the unfolding of his views on etherification, and on the constitution of salts, which may be truly said to have laid the foundations of modern organic chemistry. All those of his pupils who then made up their minds to devote their lives to chemistry, whether in the walks of the pure science or in those of its applications, must willingly own that much of the success which they may have met with in after years is due to his teaching and example; and admit that in the receptive period of a man's life the influence exerted upon them by a teacher whose years were not far removed from their own, of high aims and of ardent temperament, could not fail to be inspiring. This is not the occasion to inquire into the position which Williamson holds as one of the great chemists of our time and country. Rather is it our object now to express the feelings of gratitude and, if I may be allowed to say so, of affection, which we, who have been his pupils and are his friends, as well as those of us who can only claim the latter but perhaps no less intimate relationship, entertain towards him; to assure him that we look back upon the times spent in the laboratory with him as some of the pleasantest as well as some of the most fruitful of our lives. And both pupils and friends here join to show their appreciation of his labours and of his character, and to acknowledge the debt which they and their science owe to him. This portrait, sir, of our friend and master, finds a fitting resting-place within the walls of the College in which his working years were spent. It will remain as a memorial of a teacher, an investigator, and a colleague, whose main interest was to uphold and increase the renown of University College as a centre of intellectual progress, and of one whose character, both as a man and as a chemist, future generations, like our own, will delight to honour. It is now my pleasing duty to unveil the portrait, and to ask you, sir, as the President of this College, to accept it on behalf of the subscribers.

The portrait was then exposed to view.

The President said:—In the name of and on behalf of the Council and members of this College, I accept with gratitude this admirable likeness of our dear colleague and friend, Dr. Williamson. Sir Henry Roscoe has truly said that this is not the place to dilate on Dr. Williamson's great scientific merits, and the great claims which he has as a scientific man to any honour that could be bestowed upon him. I shall not venture on this subject, but I may say this: that looking at Dr. Williamson's career, as I can do, for the last forty years (thirty years of which he has been connected with this College), there never was a man more loyal to this institution, and more devoted to its best interests, than Dr. Williamson. The business of a Professor here is not only to teach, but to take part in the management of the College, which, as you know, devolves individually and collectively upon them. It is in the meetings of the Council and the Senate that the devotion of the Professors to the interests of the College is shown quite as much as in the teaching of classes. The College could not be worked without the business aptitude of the professorial staff; and in this duty of management none showed more zeal, loyalty, and devotion, during thirty years, than Dr. Williamson. We as a governing body must feel deeply indebted to him for the interest which he has shown in the welfare of this institution. But I should not be doing my duty if I were not to couple with his name that of his wife. Mrs. Williamson was as devoted as her husband, and did very much to raise the character of the School. She showed the greatest interest and enthusiasm in all the work which as a woman she was able to perform, and to bring about harmony within the walls of this institution. Mrs. Williamson worked side by side with her husband with unwearied devotion in, as I have already said, the best interests of University College. Ladies and gentlemen, I can only add in my own name, and in the name of this institution, the hope that Dr. Williamson and Mrs. Williamson will be followed with all health and happiness in their comparative retirement from further active work.

Sir Frederick Abel said:—Allow me to move a vote of thanks to the President of the College for his kindness in being the mouthpiece of many old friends in expressing as he has done the high respect and great affection entertained for Dr. Williamson by all his old colleagues. I desire to add that it is a great pleasure to me to be able to assist at this ceremony; and I, for one, am highly gratified at the life-like portrait presented to the College and accepted by you, sir, as President, on its behalf.

Dr. T. Anderson seconded the vote of thanks proposed by Sir Frederick Abel.

The President briefly acknowledged the compliment which had been paid him.

Dr. Williamson (who was received with cheers) said:—"I believe, sir, that the reward which upon the whole is most satisfactory (and which perhaps I may call the highest) which can be given to the man who has endeavoured to do his duty, is the expression of approbation from men of high authority on the subject-matter on which he has worked. The compliments which have been paid to me to-day have been enhanced greatly by some words which Sir Henry Roscoe let fall, and which could not have come with greater weight from anyone than from my old friend. It is to me a proud feeling—one which gives me great satisfaction—that in the decline of my life, and the end of my career, I should, from such a man—a man of such high character and position—have received so cordial and friendly an expression of approbation and personal esteem. I must ask leave, sir, to thank the Council, and you as their head, for the honour which you have done me in allowing my portrait to be placed within these walls; for although I have been associated with other colleagues, and have performed duties of other kinds, there is no place that I have felt it so great an honour to be connected with as University College. Here I have been associated with many men who have made noble self-sacrificing efforts in the best interests of this institution. I look back with pride on my connection with my colleagues of this College, though I have often bitterly regretted that my intercourse with the students has not been more personal. Sometimes a man comes up to me, shakes me by the hand, and calls me by my name, and I am obliged, to my shame, to confess that I do not know his name, which I am obliged to ask, and then I find he was an old student who knew me perfectly, remembered my lecturing in a long dark room, in which I was visible

to him, though he was not visible to me. I have often very much regretted that I have not been brought into closer relations with this large body of earnest men and students. Still, among those whom I have known I have found many esteemed friends. I do not think it desirable for me to make further remarks, beyond expressing to Mr. Collier my appreciation of his success in making what is not an ugly portrait out of such an ugly face as mine.

The proceedings then terminated.

In the evening Dr. Williamson was entertained at dinner at the Freemasons' Tavern by a goodly number of his friends and old pupils. Sir Henry Roscoe presided. After the toast of the Queen had been given and duly honoured, Mr. Carteighe, one of the honorary secretaries, announced that a considerable number of letters from subscribers had been received, expressing their regret at not being able to be present. The one from Prof. Michael Foster, F.R.S., referred humorously to Dr. Williamson as the "Ether Meister."

Sir Henry Roscoe, in proposing the toast of the evening, "Our Guest" (Dr. Williamson), alluded in kindly and affectionate terms to his early association with him, to his enthusiasm as a teacher, and to the respect in which he was held by men of science all over the world.

Dr. Williamson, in replying, expressed the gratification which their hospitality and kindness had afforded him, and referred with pride and satisfaction to the great honour which had been conferred upon him in the presentation of his portrait to University College. In conclusion, he invited any of his old pupils, present and absent, when in the neighbourhood of Hindhead to call and see him in his "nest."

Mr. Norman Lockyer, F.R.S., proposed "University College and its President," and Mr. J. Eric Erichsen, F.R.S., the President, replied.

Prof. W. H. Flower, F.R.S., submitted "The Professors of University College." Prof. Henry Morley responded for the Arts Faculty, and Prof. G. C. Foster for that of Science.

Prof. Ramsay, F.R.S., proposed "The Chairman," and Sir Henry Roscoe, M.P., responded.

Prof. T. E. Thorpe, F.R.S., proposed "The Committee of the Williamson Testimonial," to which Mr. Michael Carteighe, President of the Pharmaceutical Society, and Dr. H. Forster Morley, the honorary secretaries, replied.

THE MORPHOLOGY OF BIRDS.[1]

II.

THE second part of vol. ii. is taxonomic and systematic. The author criticizes and tests the taxonomic value of the numerous characters of all the organic systems; each paragraph forms therefore a condensed *résumé* of our present knowledge of the various organs, with especial reference to those parts which proved to be of more than ordinary taxonomic importance. The question if an organ is of taxonomic value at all does not depend upon the presence or absence of the organ itself, but upon what it is like. Hence the weakness of those systems which have been based upon positive and negative characters only; even Garrod failed, since he took for his guidance not quality, but merely quantity. Those organic characters are preferable which exhibit a certain amount of differentiation, but which at the same time do not vary much within the limits of smaller groups of birds. Through combination of a considerable number of such characters, to be taken from organs between which there can be but little correlation, we have the best chance of arriving at a sound system. But of such characters there are, unfortunately, few.

However, on pp. 1580–91, Fuerbringer has selected forty-eight characters, not all, of course, of equal value, and has arranged them in tabular form, together with the ninety families into which he divides the birds. Especial attention may be drawn to the second column, which contains the first known occurrence of fossil members of each of the families. This column, together with the remarks on pp. 1107–10, and the discussions under the heading of each family in the special systematic part of the book, contains the only complete and critical essay on fossil birds that has yet been published.

But it is impossible to give here anything besides occasional hints about the vast amount of thought which the author has bestowed upon nearly all the organic systems, always on the look out for characters which might perhaps prove constant enough to act as guides amongst the chaos of the natural affinities of birds, always awake where great adaptiveness or convergence of forms might easily lead us astray.

Bill and feet proved to be of comparatively little value, in spite of their historical significance; the same applies to the oil-gland; whilst pterylosis is never to be neglected, especially that of the embryo.

Oology.—The size of the eggs depends upon the terrestrial, aquatic, or aërial life of the birds. Those which make their nests in high trees lay, as a rule, smaller eggs, and are "altrices"; whilst those which lay the eggs on the ground, and are "precoces," have more and larger eggs. Thickness of the shell, or the weight of the egg, often depends upon the smaller or greater liability of the eggs to external injury. The colour of the eggs stands, like that of the female bird, in correlation with the configuration of the nest, and affords good characters for classification. The best character, however, is formed by the finer structure or texture of the shell, since this remains unchanged in the species, and can also successfully be used for the recognition of wider relationship.

Skeletal System.—The importance of relative measurements has induced the author to look for a unit applicable to all birds. This he finds ingeniously in the average length of the dorsal vertebræ, because of the constancy of these parts. The numerous tables, which contain (pp. 794–800) an enormous number of measurements, have shown, however, that their taxonomic value is but very limited. The total number of vertebræ is inconstant even in the individual, and varies in larger groups to such an extent (Limicolæ 43–50, Anseres 50–63) that it can hardly be used in determining the systematic position of a given bird. Better results are yielded by the numbers of the cervical, thoracic, and sacral vertebræ alone, and their proportionate quantity, cf. Table xxii. pp. 778–79.

In the configuration of the sternum, the anterior margin, with its spine, is the most noteworthy point.

Of greater value is the configuration of the maxillo-palatine apparatus, as was first pointed out by Nitzsch, J. Mueller, and especially by Cornay in 1847. Huxley's classification, based upon these characters, in 1867, marked an epoch in the systematics of birds; but it is artificial, not natural, as the numerous exceptions and intermediate stages show, which have been discovered by later anatomists. The basipterygoid processes likewise afford gradual differences only. The whole maxillo-palatine apparatus is far too adaptive to permit of its use as a safe guide in classification.

The hyoid bones afford a rather good generic, and occasionally even a family character.

The size of the coraco-scapular angle depends in inversed ratio upon the development of the shoulder-muscles. This, with the various dimensions of the scapula, the processes and foramina of the coracoid, &c., receive special attention in the tabular lists, pp. 738–57,

[1] "Untersuchungen zur Morphologie und Systematik der Voegel. zugleich ein Beitrag zur Anatomie der Stuetz- und Bewegungsorgane." Von Max Fuerbringer, Professor der Anatomie, und Direktor des anatomischen Institutes und des Museum Vrolik der Universitaet zu Amsterdam. Mit 30 Tafeln. (Amsterdam: T. van Holkema, 1888.) Continued from p. 152.

and in the text of the osteological part of the book. Table xxxvii. contains the length of the humerus in units of dorsal vertebræ.

Pp. 1042–47 form a condensed essay on the pelvis. The difficulties of homologizing its constituent parts with those of other Vertebrata are pointed out, but they are not solved. The pelvis, as a whole, has never been tested sufficiently as to its taxonomic value, and the adaptability of the limbs, both anterior and posterior, warns us not to lay too much stress upon these parts either.

Pp. 1053–66.—Fuerbringer points out which muscles are of systematic importance, also how far and in which groups of birds he found them to be so.

The results yielded by the most extensive examination of the brachial plexus (pp. 232–80, Plates 8–10) are morphological only, but of no taxonomic value.

In his treatment of the sense-organs, the digestive, vascular, excretory, and reproductive systems, he gives only a more or less cursory review of the work of other anatomists. The organs of voice and respiration receive more attention. The author distinguishes between (1) syrinx trachealis, possessed by the Passeres tracheophonæ, and in a less finished degree by certain Pelargi; (2) s. tracheobronchialis (Psittaci, Passeres, Pseudoscines = Menura and Atrichia); (3) s. bronchialis, many Cuculidæ, Caprimulgidæ, Strigidæ, &c.

Concerning the ontogenetic development of birds, Fuerbringer has been struck with the extraordinary resemblance which the embryos of certain families exhibit to each other before the divergence of the final formation of beak and feet has been fixed. Thus, Laridæ and Limicolæ, Pici and Passeres, Striges and Caprimulgidæ, indicate in these stages close relationship.

Remarkable, although rather short (pp. 1107–19) are the chapters on palæontological development and on geographical distribution. The hypothetical division of the world into Arcto- and Neogæa is not favoured, whilst Lemuria is justly re-established. Explanations of the present distribution of the Ratitæ, Spheniscidæ, Rasores, Passeres, and other principal orders are attempted, and if not always successfully solved, are at least partly cleared up by the allusion to fossil intermediate forms.

The cradle of the Passeres is very old, of Cretaceous age, and existed probably in the Oriental region; the Eurylæmidæ still exist as the last and least modified descendants of the primæval Passeres. Thence they spread all over the globe. About the beginning of the Miocene age one stock branched off, likewise in the Oriental region, as the Oscine type, the numbers of which conquered the world, with the exception of the Neotropical region, which they reached last, and found already fully occupied by their older but highly developed relatives the Oligomyodi and Tracheophones.

The outcome of all this work is a most elaborate systematic arrangement of birds, recent and extinct. This occupies pp. 1136–1591.

Family after family is discussed as to its characters, affinities, distribution, first fossil occurrence, and the position it held in the opinion of previous ornithologists and anatomists.

Fuerbringer's system of birds is almost entirely new, less striking in the arrangement of the families and the placement of odd or solitary genera than in the disposal of the whole host of birds into a few large orders. Such a grouping together has been a long-felt desideratum, because the close adherence to the principle "*Divide et impera*" has led to a splitting up of the birds into an ever-increasing number of groups, whilst their combination into greater phyla was in danger of being lost sight of.

This want of generalization made us hail the terms Schizo-, Desmo-, Ægitho-gnathæ; but they were hardly established as household words amongst ornithologists before Schizorhinæ and Holorhinæ, Homalogonatæ and Anomalogonatæ, went through their short-lived existence, and in their turn gave way to other principles of classification by Garrod and Forbes, which will easily be detected in the system now before us. The class Aves is divided into two sub-classes, eight orders, twenty-four sub-orders, forty-five gentes, and ninety families. The orders, especially the four into which the Carinatæ are divided, represent such centres or phyla as we have been longing for, and around them are arranged other, mostly aberrant or much specialized, groups as "intermediary sub-orders." The orders end each in *-ornithes*, the sub-orders throughout in *-formes* (see table on next page).

This system of birds is graphically illustrated by two side views of an elaborate "ancestral tree," on Plates 27*c*, 28, and by three more plates which represent three horizontal sections through this ideal tree. The author justly insists upon the necessity of constructing such ancestral pedigrees in the three dimensions, and he has himself taken care to indicate isomorphism, *e.g.* Gypogeranus and Cariama, Procellariidæ and Steganopodes, by the convergence of the branches.

It is, of course, beyond the scope of this review to enter into many of Fuerbringer's ideas on the affinities of all the families of birds. Only those of general interest can here be dealt with.

The old group of the *Odontornithes* has properly been discarded; their constituent members have been distributed amongst the other birds. Probably all birds possessed teeth during the Cretaceous epoch.

Archæopteryx belongs to the primitive Carinate flying birds or Proto-Ptenornithes. It cannot be decided whether it is a direct ancestor of living Carinate birds; but there are no valid reasons why it should be looked upon as an intercalary type between reptiles and birds.

We learn more about the Ratitæ. They are Deuter-Aptenornithes, *i.e.* they are descendants of Ptenornithes, but have lost their power of flight. The differences between the various forms which are generally recognized under the name of Ratitæ are so great, that these birds cannot collectively be opposed to the Carinatæ. Struthio, Rhea, and Dromæus Casuarius are each representatives of separate orders. Fuerbringer approaches the views of Sir Richard Owen, who more than twenty years ago suggested that the various Ratite birds are the descendants of several groups of the Carinatæ, but that they have become modified in similar directions: their Ratite characters are cases of analogy, and do not indicate near relationship. The separation from the common Carinate stock took place very early, certainly as early as the Cretaceous epoch. The root of the Struthiornithes perhaps contains fibres of the later Pelargornithes, whilst the Rheornithes and Hippalectryornithes have also some traces in common with the primitive or dawning Charadriornithes and Alectorornithes. Lastly, the New Zealand Ratitæ, Apteryx, and Dinornis resemble the Carinatæ in so many features that they form only the sub-order Apterygiformes of the order Alectorornithes. The affinities of Apteryx with the Crypturi and Fulicariæ are even greater than those with the other Ratitæ

For Carinatæ the synonym Acrocoracoideæ has been invented, but the author does not see his way to accepting them as a separate sub-class, since he had to break up the Ratitæ.

The most primitive forms amongst the Ornithuræ are the American Cretaceous Ichthyornis and Apatornis. They differ from recent Carinate birds in degree only, viz. by their tormodont teeth and amphicœlous vertebræ. They stand nearest to the Laridæ, with touches of the Procellariidæ and Ciconiiformes.

Hesperornis has most probably lost the keel of its sternum, and in correlation with this loss has also acquired platy-

CLASSIS AVES.

I.—Subclassis Saururæ.

coracoidal features; it would therefore have to be grouped with the Ratitæ if we wanted to degrade this expression to a collective term for cases of converging analogies or isomorphism, and thus deprive it of any phylogenetic meaning. The characters which mark Hesperornis as an Aptenornith are secondarily acquired, whilst all the rest of the skeletal characters indicate its close affinity with the European Enaliornis, and amongst recent birds with the Colymbidæ and Podicipedidæ. This relationship receives its final expression by the establishment of the order Podicipitiformes.

These Podicipitiformes, with the Anseriformes and with the Ciconiiformes, are combined in one big order, *Pelargornithes*. In proportion as the first two of these orders appear circumscribed and natural the Ciconiiformes appear heterogeneous They are made to contain the Phœnicopteri, Pelargo-Herodii, Steganopodes, and the Accipitres or diurnal birds of prey. The close affinity of the Phœnicopteri with the Pelargi is beyond doubt, and so is that of the Storks and Herons, and that of the latter with the Steganopodes. But how the Accipitres should be related to the other three or four gentes seems less clear. However, we must not forget that already Garrod had arrived at similar conclusions. Fuerbringer holds that the Cathartidæ are a very old and now declining Raptorial family, and that they have many structural points in common with the Ciconiidæ, whilst the Gypofalconidæ exhibit genetic relations with the Steganopodes (Fregata) and with the Ardeidæ. Gypogeranus had formerly (Miocene of France) a much wider distribution than now, and it is the last remnant of a group which branched off from the common Accipitrine Stork before the division into Cathartidæ and Gypofalconidæ took place.

Steganopodes are known to have existed in the earliest Eocene period, and are now on the decline; lowest amongst them stand now the Phætontidæ, highest the Fregatidæ. Their rather striking affinities with the Accipitres have already been mentioned, perhaps they are as distantly connected with the Pelargo-Herodii.

Pelargo-Herodii.—Plataleidæ form the lowest type, and afford some points of connection with the Limicolæ; Ardeidæ, the highest and most flourishing family, exhibit various characters by which we might trace their pedigree towards the roots of Colymbus, Haliæus, Falco, and others. This diversity of connections indicates either

that the Pelargo-Herodii are an extremely old group, which has preserved features common to all the other Pelargornithes, or that the division into the various much specialized gentes took place rather recently. Fossil material seems to favour the latter view, and this circumstance probably explains why the Ciconiæ have more in common with the Cathartidæ, whilst the Ardeæ approach the Steganopodes and Falconidæ. Why the Flamingoes should be elevated to the rank of a gens does not appear clear, considering their close genetic connection with the Pelargi, especially through the Miocene Palælodus.

Anseriformes.—Probably an old and small pre-Miocene group, which has marked its broader development more recently. The Eocene Gastornis seems to have been a gigantic type, which had lost its power of flight, like the diluvial Cnemiornis of New Zealand. Amongst recent Lamellirostres, Mergus is the lowest, Cygnus the highest type; they are distantly related to the Podicipitiformes.

Palamedeiformes show many connective points with the Anseres, Steganopodes, and Pelargo-Herodii, but their reception into the Pelargornithes is rendered impossible by various fundamental and primitive peculiarities. Through their intestines and pterylosis they somewhat resemble Rhea. Whether we place them nearer to the Anseres than to the Pelargi and Steganopodes depends upon the taxonomic value which we happen to attribute to their skeletal, muscular, intestinal, or external features.

The Antarctic *Aptenodytiformes*, s. Spheniscidæ, are a very old family, because the genus Palæeudyptes shows that they had become specialized into diving and swimming birds with total loss of the power of flight in the Eocene period, or probably even earlier. Fuerbringer calls the Penguins Trit-Aptenornithes, indicating that they, like the Great Auk, the Dodo, Ocydromus, and others, have lost their power of flight later than the Ratitæ. A sharp line between Deutero- and Trit-Aptenornithes cannot, however, be drawn, since Cnemiornis, Gastornis, &c., are intermediate forms, just as Stringops is now on the way to become Aptenornithic.

Many of the characters of the Penguins generally considered as primitive are partly "pseudo-primitive," *i.e.* phylogenetically reduced and ontogenetically retarded; *e.g.* the structure and distribution of the feathers, the fin-like anterior extremities, the broad scapula, and, according to Fuerbringer, even the metatarsus. The resemblances with Podiceps and Colymbus are superficial only, but he cannot tell to which of recent birds the Penguins approach nearest. All that the author contends against is the removal of the Penguins into a sub-class, equivalent to the rest of the Carinatæ. On Plate 29*a* they are represented as a lonely group.

The *Procellariiformes*, or Tubinares, have likewise the rank of a sub-order, intermediate between Steganopodes, Ichthyornis, Spheniscidæ, and Charadriiformes. They are certainly a very old and now isolated group.

The large order of the CHARADRIORNITHES has split into aquatic and gralline types. The Alcidæ are closely allied to the Laridæ, and are probably the most recent of those birds which have assumed a pre-eminently aquatic and diving life, with correlated reduction of the wings. They are restricted to the periarctic zones of the northern hemisphere, whilst their relatives, the Gulls, enjoy a cosmopolitan range. There can be but little doubt that the oldest *Charadriiformes* were gralline, so that the Otides, with Œdicnemus, Parra, and the Thinocoridæ, stand nearer the common stock than the more specialized aquatic members.

The *Gruiformes* are connected with the Charadriiformes by Eurypyga, with the Ralliformes by Aramus. They seem to have reached their culminating period in the Miocene age. Dicholophus is the most highly-specialized form, and has assumed peculiar Raptorial characters isomorphic with those of Gypogeranus, which is a true bird of prey.

The *Ralliformes* flourished as early as the Eocene period. The Fulicariæ, consisting of the Rallidæ and Heliornis, are more nearly related to the Hemipodii than to the Crypturi. The sub-order of the Ralliformes takes, therefore, a position intermediate between Gruiformes, Crypturiformes, and Apterygiformes.

The latter two sub-orders, together with the Galliformes, constitute the order ALECTORORNITHES.

The relationship of the Crypturi with the Apteryges is real, and bridges over the gulf between Carinate and Ratite birds, especially through cranial and pelvic structures.

The *Galliformes* proper consist of three families: Megapodii, of Austro-Malayan distribution; Neotropical Cracidæ; and universal Gallidæ. The two former exhibit so many important differences in their soft parts that, in spite of their numerous skeletal resemblances, they cannot be opposed to the rest of the Fowls as Peristeropodes. Closely allied to the Galli is Opisthocomus, an old type now dying out; the last solitary species has reached a high degree of one-sided specialization, which elevates this bird above its nearest allies to the level of low arboreal birds.

Columbiformes stand between Charadriiformes and Peristeropodes, perhaps nearer the former through the Pterocletes, which are undoubtedly the more primitive group, whilst Columbæ, beginning with the Miocene only, are still on the ascending scale, and are birds of the future. Didus and Pezophaps are degenerate Columbæ, not necessarily very old forms.

Psittaciformes.—The affinities of the Parrots have puzzled Fuerbringer as much as other ornithologists. He places them as an intermediate sub-order, like the Columbiformes, between the Alectorornithes and Coracornithes. Our knowledge of fossil Parrots is very defective. They existed in the Lower Miocene of France, typically developed; now they are a large, numerous group of birds, with more than intertropical range, and with no living members through which they approach other groups.

The last great order is that of the CORACORNITHES.

The *Cuculiformes* = Musophagidæ and Cuculidæ, are connected with the ancestral Limicolæ and Galli; however, their roots meet so distantly, certainly not later than the earliest Eocene period, that these birds have gone along parallel lines of development since those remote times, and that the Cuculiformes cannot be classed with either Galliformes or Charadriiformes. Their original centre was probably the Oriental region, whence they spread chiefly in Western directions.

The *Coraciiformes* are relatively least removed from the Charadriiformes. The Coraciæ represent the lowest group of arboreal birds, and are related to the Caprimulgi, more remotely to the Owls, Trogons, and Bee-eaters. The Caprimulgi include necessarily the Podargidæ and Steatornithidæ, whilst their apparent similarity with the Cypseli rests chiefly upon secondary analogies. The same applies to the Striges with reference to the Accipitres. Owls have so many important points in common with the Coraciæ (Leptosomus), and especially with the Podargidæ, that they have to be looked upon as Raptorial Coraciiformes or "Podargoharpages."

Halcyoniformes.—The Halcyones, Meropes, and Bucerotes—the latter of course including Upupa—form a pre-eminently palæogæic group of syndactylous birds. The Todi, including the Motmots, connect them with the previous and with the next following sub-order. The same applies to the Trogons.

Pico-Passeriformes.—This large sub-order contains the Pico-Passeres, Makrochires, and the Colii. The Colii have frequently been classed with or near the Musophagidæ, Fuerbringer thinks owing to superficial analogies only. They are now a very lonely little group in the Ethiopian region, without any known history, or without

satisfactory indications of their pedigree, their affinities with the Cypseli being perhaps the least far-fetched.

The *Makrochires* = Cypselidæ + Trochilidæ, prove to be far more closely related to the Passeres than to the Caprimulgi. The old group of the "Cypselomorphæ" had therefore to be broken up.

Pico-Passeres.—Very intimate relationship connects the Indicatoridæ, Capitonidæ, Rhamphastidæ, and the Picidæ to one group—*Pici.* Primitive Pici existed in the Eocene age; many threads bind them to the Galbulæ and to the Halcyones, still more to the Pseudoscines.

Passeres.—They represent the highest types which the avian stock has as yet developed. In spite of their enormous number of genera and species, which surpasses that of all the rest of the birds, they agree so closely with each other in all their principal and primary characters that the Passeres proper are morphologically only of the value of one family. This uniformity has naturally always rendered their further classification very difficult.

Fuerbringer divides them as follows, in close conformity with the views held by most English ornithologists.

I. Family *Pseudoscines* = Atrichia + Menura.—They are types which are now dying out, and which differ from all other Passeres through those characters which they have in common with the Pici.

II. Family *Passeridæ*, with four sub-families.

(1) Desmodactyli = Eurylæmidæ.—They differ fundamentally from the Coraciæ, and are the last remnants of the oldest Passerine forms.

(2) *Oligomyodi.*—Their wide distribution—*e.g.* Pitta in the Oriental and Ethiopian regions, Xenicus in New Zealand, the overwhelming majority in the Neotropical region—sufficiently indicates the extreme age of the Oligomyodi, and sufficiently accounts for the great diversity in the development of the syrinx, podotheca, and femoral artery, &c., which makes these birds appear a rather heterogeneous group.

(3) *Tracheophones.*—The tracheophonous syrinx, and the entirely Neotropical distribution of the Conopophaginæ, Pteroptochinæ, Formicariinæ, Furnariinæ, and Dendrocolaptinæ, suggest a monophyletic origin of these birds from lower American Oligomyodi.

(4) *Oscines* s. *Acromyodi.*—This family forms what may be called the topmost branches of the avian tree, with the Corvinæ as its culmination. It is characterized by the diacromyodean syrinx, and by the bilaminate covering of the tarsus. The latter feature occurs, however, also in the tracheophonous genus Heterocnemis, and is absent in the Alaudinæ.

Regarding the development of these four sub-families of the Passeridæ, the reader may be referred to a previous page (p. 178) of this summary.

Most probably all birds are the descendants of one reptilian form, though of which we do not know. The first lizard-like birds were small, and very likely terrestrial. They diverged into climbers on rocks and trees, and into inhabitants of swampy regions. The latter stock gave rise to swimming birds. The first birds were not vegetable feeders, as is generally supposed, but lived on insects and other small Invertebrata.

Lastly, there arises the question: What are the reasons for the natural extinction of large birds? Not predestination or catastrophes.

High differentiation, possible only through the one-sided development of certain organic systems and correlated regressive metamorphosis of the others, has, in the older groups of birds, frequently led to increased size of the body. This size, although securing a predominant position to the birds for the time being, inevitably implies the turning-point in the height of their development Large or highly specialized animals will be least able to adapt themselves to further changes of their never-stationary, ever-changing surroundings, because, through their very one-sidedness, the retrograded as well as the most specialized organs have rendered the whole organism more fixed than is the case with lower or less differentiated and therefore still plastic contemporaries. Amongst the younger groups of birds such a large size as is common amongst old and isolated types has not yet been reached, and probably will always be avoided. Small, but equally developed, will be the birds of the future.

So far so good. But with all this praise, are there no faults in Prof. Fuerbringer's work? Certainly, there are some. Its greatest fault may be indicated and at the same time explained in one sentence. If the author had been able to devote another year's labour to his "Epoche machenden Untersuchungen," he probably would have written a smaller book. H. GADOW.

MUSINGS ON A MEADOW.

TO the general observer nothing in the way of vegetation would appear to present so few aspects, so limited a scope to the imagination and the associative faculties, as an expanse of herbage; and yet, perhaps, nothing that bountiful Nature has provided for the use and service of men so teems with the variety of associations that it presents to each different mind.

The farmer, whether he be the farmer of England, the wandering Bedouin, or the ranch-man of the New World, looks at the broad pastures and far-stretching plains, but not to admire the mingled masses of gorgeous colours, not to speculate upon the battle that may have been fought upon this spot or the scenes that have happened there in former times, not to separate the numerous varieties of grasses into their many botanical genera and species, but to calculate how many sheep he can feed to the acre upon it, whether there is enough of white clover to fatten his camels upon, or whether his horses will have a sufficiency of suitable food to graze upon. The wide wild waste of endless lines of pale yellow, red, and gray, conveys no pleasure, but merely the indication of a good soil; and the buttercups and daisies he sees in the pasture meadows of England, hallowed by songs and memories, are to his economic eye positively offensive; knowing, as he does, that the older these buttercups grow, the more distasteful they become to stock, but never stopping to discover that it is because they become more acrid. To him it would seem a species of legerdemain if a botanist were to say to him, pointing to a buttercup, "Dig that up, and you will find a tuber at the root," and were then to select another, apparently similar in appearance to the former, and were to tell him that it had no tuber at the root; for from his eyes are completely hidden those minute differences so easily seen by the specialist between *Ranunculus bulbosus* and *Ranunculus acris.*

The botanist, on the other hand, as his eye rests on the same spreading plains of green, is utterly regardless of the feeding value of the plants that he sees before him. As he wanders from country to country, his eager eye detects the diminution or increase of particular species in different latitudes and altitudes, searching out the truths of Nature, or watching with a view to the confirmation of some pet theory. His mind ranges over the different prairies, plains, and meadows of the world. Again the battle of plant life is waging for him. His delight is unbounded. Every plant has its own history, so evident to him, so abstruse to the mere superficial observer; and, involuntarily, associations crowd upon his mind, of some musty tome perchance, or some ancient and not very accurate plate, or some amusing anecdote. For example, the cactus in the plains of Arizona or Texas reminds him of the many times he has seen this genus portrayed in pictures of the Holy Land at the time of the Founder of Christianity, and how, even in books pretending to be learned, he has met with it in the description of the plants of Syria of 2000 years ago, although, as a matter of sober history, this

plant was only introduced into the Eastern Hemisphere after the discovery of America, in which continent the cactus is indigenous. Even if he be colour-blind, and the petals of the blazing poppy show to him the same tone as its sober sepals, yet he is still able to admire the beauty of form, which conveys to him the history of the development of the plant from its seed, and he would still be in the position to give a discourse interesting to the uninitiated though intelligent observer; and at the end of an hour's conversation, in common with others, he would be compelled to exclaim that there was still much in the life of the plant of which he was utterly ignorant—so limitless are the subtle workings of Nature!

But what does the artist care for either of these views? He cares not for the fattening of stock. He feasts with rapture on the different grays, greens, yellows, blues, and reds, that are spread out before him, and on the delicate tints and shadows cast by every passing cloud. He cares not to know of the buttercups and daisies that grow there; it would even distress him to tell him that the yellow-greens are groups of fescues, and the blue-greens patches of cock's-foot and fox-tail. What is that to him? He was wondering what colour in his box would reproduce those delicate tones. He does not seek to know how much corn to the acre that meadow would grow if ploughed up, nor how much it might once have grown. To him it is merely one endless feast of colour.

Perchance more sordid ideas of another kind may occur to him. Apprehensions as to the hanging of his picture may dispel his rapture in Nature's handiwork, and his mind may be occupied with a fear lest the red ground of his neighbour's picture will kill his own more delicate tones. Pounds, shillings, and pence, the cares of a wife and family, are apt to destroy for a time the beauties of Nature.

How happy is the man who sketches and sketches only to reproduce for himself these works of Nature; whether they be the meadows of England, dotted with short-horns and Hampshire Downs, and bounded by the rook-sheltering elm; or the plain of Megiddo; or the boundless prairie of Manitoba.

How differently again would the antiquary survey the self-same scene! His mind would revert to the people who trod these plains in days of yore. Their history, manners, customs, dress, and social habits, would open out to him a wide field of speculation. On this very pasture contending armies may once have trod, and the ebbing life-blood of patriotic heroes once have flowed. His eyes may be resting on a Bannockburn, or a Worcester, or a spot where the Carthaginians of old strove against the might of Rome, and were worsted in the fight. Here the chariots of the Egyptians may have rolled, or the devoted Aztecs have struggled hopelessly against their Spanish conquerors.

The contemplation of the plains produces in him yet another train of thought. He conjures up an historical novel or poem, but finds he has merely repeated the ideas he has read before: he casts them aside and starts afresh; and still he envies the artist the ever-changing phases, and the botanist the unsearchable workings, of Nature. To him there are limits fixed and defined: his speculations are restricted to the period of man's existence on this globe, but for the painter and botanist the range and variety of subject are illimitable.

Thus the pasture and the prairie grow up and die away, containing, like most things in this world, their quota of good and bad. Some weeds go unregarded; the pernicious effects of others become so prominent that they are recognized at once and hated accordingly, like the grass *Cenchrus tribuloides*, which bears a prickly fruit that winds itself into the wool of the sheep, and renders the rearing of sheep where it exists impossible; while other plants, such as clover, and the blue grass, arrest the attention of even the careless agriculturist by their manifest merits.

Now, to all, these herb-clothed portions of the earth offer themselves in various phases according as the mind is prepared to receive them; and happy is he who can so adjust his mind, and concentrate his thoughts upon the phase required; though so devious are the paths of Nature that he will often travel far, and then, as a man traversing a labyrinth, be checked by some such knotty question as: "How does a plant obtain its nitrogen?" and he will have to return to the post from which he started. And such are the difficulties which have deterred those who have written on the formation of pastures from going further on their course. They have rested content with a description of the peculiarities of each plant.

But to him who tries, both as botanist and agriculturist, to fathom the mysteries inseparable from a meadow, whether in the New or the Old World, difficulties present themselves "not in single spies but in battalions." Nature alone supplies enough subjects for the closest study and investigation: depth of soil, worms, showers, dews, periods of drought, periods of wet, grubs, birds,—each and all arrest the mind, and claim due consideration. And when to these are added difficulties of man's own providing, necessary though they be, the solution seems to become a hopeless problem. Now no longer is the battle of plants waged merely with the weather and their other natural antagonists, as they may be fitly called; no longer is the struggle modified into the simple solution of the survival of the fittest; for the farmer produces new enemies to pasture in the shape of stock and the scythe, for cattle select the plants they like best and leave the worst to seed, and the ruthless scythe exposes the delicate stem to the heat of the sun.

An opportune shower has preserved a field from the pernicious effect of soft oat grass (*Bromus mollis*), by thus rendering it palatable to stock, and so preventing its seeding, while the want of rain has caused a meadow, almost contiguous, to be impregnated with this obnoxious weed.

The struggle of plant life is always waging in a pasture, and unless the issue of the battle is directed by animals or men, the most vigorous get the upper hand.

Nature, with her customary and marvellous counterbalancing characteristics, has foreseen this possibility and provided against it, for in a wet season stoloniferous grasses (whose travelling shoots have then the power of sending innumerable roots into the ground, each to become a parent plant) cover the ground to such an extent that the superficial observer is tempted to declare that the meadow which he views is entirely composed of creeping grasses. On the other hand, in a dry season, deep-rooted plants such as tall fescue (*Festuca elatior*) gain the mastery and apparently oust their opponents. The vigorous grasses characterized by an underground growth, such as fox-tail (*Alopecurus pratensis*), and which are amply provided for by Nature in respect of hardihood when growing, are scanty seed-bearers; and even when they do perfect their seeds, so small is the store of food contained in them, compared with their immediate neighbours, that a large percentage of them germinate only to wither away. Rye-grass and the smaller dog's-tail (*Cynosurus cristatus*), deprived of other means of reproducing their species and fostering them, bear seeds that are eminently qualified to reproduce themselves.

Let him, therefore, who essays to unravel the mysteries of our green meadows remember to cultivate to the acutest degree the faculty of ocular observation, for

> "Segnius irritant animos demissa per aurem
> Quam quæ sunt oculis subjecta fidelibus, et quæ
> Ipse sibi tradit spectator."

Let him also learn to employ and utilize the intelligence of others; and above all let him not be surprised if, after much patient study and investigation, his heart sinks

within him, appalled before the host of difficulties; as when, for example, the shadow of a passing cloud on a sunny day reveals to him the individuality of the 400 plants in each square foot of pasture, which have before escaped his attention, and the thought flashes across his bewildered mind of the 400 parts played by each plant, and the 400 times 400 causes that effect them. Almost hopelessly he perceives that the knowledge which he is in search of, and which he fancied he had in his hand, has eluded his grasp like a fire-fly, and left only a flash behind; and for a moment his mind is enveloped in darkness, overpowered by the infinity of Nature. The searcher after truth, however, recovers, recognizes his difficulties, recalls the object of his pursuit, returns to it with renewed energy, and, with unbiassed mind, records his observations day by day.

ALPINE HAZE.

THAT no letter has appeared on the common occurrence of this phenomenon in the British Isles is one of a thousand tokens of the small amount of interest in atmospheric phenomena taken by the public in this country. In bright days when the atmosphere at the earth's surface is nearly calm and moderately dry, the sky being nearly devoid of clouds, horizontal layers of buff-coloured haze may be frequently seen near the horizon in almost every locality in the British Isles where the air is free from the smoke of our large towns. I do not happen to have seen it nor have I heard of its occurrence on the west coasts of Scotland or of Norway. I have frequently noticed it when out of sight of land. It would be interesting to know whether it is seen at a distance of 400 or 500 miles from the nearest shore. At St. Aubin's, Jersey, at an elevation at which the French coast near St. Malo is rarely visible, a stria of this haze is often the accompaniment of mirage, the inverted image of the white-tipped rocks appearing to hang from the layer of haze, and the mirage disappearing with a change of the observer's elevation, but the line of haze remaining visible. The mirage was, when first seen, mistaken for a few minutes by some members of my family for a series of water-spouts.

I have long ago given the specific name of *nebula arida*, "dust-haze," to the phenomenon dealt with in this letter; and I still think that the English title "dust-haze" is preferable to "earth-haze," or any equivalent of the former to any of the latter in foreign languages, the latter term being too general, and capable of including the haze or mist produced by the presence of water particles. The word "dust" does not exclude organic matter, although ordinary dust-haze consists in most cases, as I think, of inorganic particles. On the other hand, any name which appears to localize the phenomenon is scarcely admissible. Dust-haze may be somewhat easily distinguished from ordinary mist or water-haze by its colour appearing of a reddish-buff tint in reflected light; and unless in complete shade from direct light, rarely becoming neutral; whereas mist usually appears gray, neutral, or bluish in reflected light, and yellow, orange, or red in transmitted. Patches—or, as they appear at a distance, bands—of dust-haze often become beds of the under surface of *cumuli*, to the formation of which clouds they then seem to bear a causal relation. As frequently in our islands, the haze is replaced during the night by stratiform clouds at its own level. In these cases there can be, I think, little doubt that the solid particles cause the precipitation of vapour. This fact somewhat militates against M. Antoine d'Abbadie's theory that the haze is really dry air, a supposition which for other reasons I regard as untenable.

Seen near the sun at sunset, bands of dust-haze are mistaken by many observers for threads of *cirrus* (what I term *cirro-filum*), and moreover the two phenomena are not uncommonly seen at the same time. As observations at sunset are useful in forecasting weather, the observers should take care to remember that lines of *cirrus* are always more illuminated in transmitted light than any species either of haze or of stratus cloud; secondly, that the *cirrus* threads appear slightly arched when viewed across the line of sight, and radiating when more coincident with it; and lastly, that a slight curl here or there very often betrays the existence of the lofty ice-cloud. I have frequently given rough sketches of these latter sunsets to observers, and these have borne a singular likeness to Antoine d'Abbadie's sketch of the dust-haze itself (NATURE, November 22, p. 79). But I do not understand this sketch, or in what sense it represents two *horizontal* bands.

In conclusion, I may perhaps be permitted to refer to two phenomena slightly related to the subject of this letter. The first is smoke. This is much more "accumulated" or less amorphous than water-dust, although its optical characteristics resemble somewhat closely those of water-dust. On the other hand, it is much more amorphous than dust-haze; and even the line left in the atmosphere by a steamer on the sea horizon on a calm day will scarcely be mistaken for dust-haze. Smoke when at a considerable elevation undoubtedly produces *cumuli* under favourable conditions. A string of ill-defined *cumuli* may be seen in the smoke of a burning forest or heath when carried a long way from land by a wind from the shore. This condensation is probably principally caused by the presence of solid particles, as in the case of dust-haze, but it may be borne in mind that a large quantity of vapour is carried up with smoke.

Lastly, the keen eye will soon learn to distinguish a peculiar haze often noticeable in England, especially over the wheat-producing districts, in fair calm weather in the month of September. This haze is also visible in some, and probably in many, parts of continental Europe. It is caused by flying Aphides, ten or more of which may be often captured in a cubic yard of air at about 10 feet from the earth's surface. In reflected light the haze has a tint of tender ultra-marine ash.

W. CLEMENT LEY.

Lutterworth, December 8.

NOTES.

MR. RALPH COPELAND, Ph. Doc., F.R.A.S. has been appointed Astronomer Royal for Scotland, and Professor of Practical Astronomy in the University of Edinburgh, in the room of Prof. Piazzi Smyth, resigned. Prof. Copeland has proved himself to be among the most skilful of modern observers.

M. DITTE has been elected to succeed the late Prof. Debray at the Sorbonne.

THE Paris Municipal Council will shortly be asked to grant the funds required by Prof. Giard to provide a laboratory and to secure the necessary assistants.

WE refer elsewhere to-day to the dinner given on Tuesday, the 11th inst., at Christ's College, Cambridge, to celebrate the completion of the ninth edition of the "Encyclopædia Britannica." The chair was of course occupied by Dr. Robertson Smith, the editor. Among the scientific contributors present were Sir Frederick Abel, Dr. Affleck, Sir Nathaniel Barnaby, Dr. Buchan, Prof. Cayley, Prof. Darwin, Mr. F. Darwin, Prof. Dittmar, Prof. Michael Foster, Dr. A. Geikie, of the Geological Survey, Dr. Glaisher, Sir F. Goldsmid, Prof. Cleland, Prof. Marshall Ward, Dr. Creighton, Prof. Greenhill, Dr. Günther, Sir Charles Hartley, Baron von Hugel, Prof. Keane,

Mr. Keltie, Prof. Ray Lankester, Mr. Norman Lockyer, Prof. MacAlister, Col. Maurice, Captain Moriarty, Dr. John Murray, of the *Challenger* Commission, Prof. Newton, Prof. Roberts-Austen, Prof. Vines, General Walker. At the close of the banquet the Chairman read letters which had been received from scholars and men of science at home and abroad. In asking the company to pledge each other in good fellowship in the loving cup, he said he could not deny himself the pleasure of saying with how much cordiality and heartfelt gratitude he and his fellow-editor, Mr. J. S. Black, and the publishers greeted the contributors, who, by their hearty assistance and their constant readiness to do far more than one had a right to expect from contributors, had made it possible for them to carry to its completion a work the difficulties of which could not be appreciated other than by those who had to edit it. Having explained the difficulty of recognizing in one toast more than a thousand English and foreign scholars, of whom not more than one-tenth were present, Dr. Robertson Smith said he would follow the example of the title-page of the "Encyclopædia Britannica" and propose three toasts—Literature, Science, and Art. In submitting the first of these toasts, he referred to the great judgment and skill of his predecessor, Prof. Spencer Baynes. Dr. Garnett responded for Literature, Dr. A. Geikie for Science, and M. Yriarte for Art. Prof. Michael Foster, amid cheers, gave "The Health of the Editor." With regard to the first editor, they would all agree with him that the qualities which Prof. Baynes had for carrying on this great work were in a certain way unexampled. His great knowledge of men and things and the fascinating way in which he made one contribute an article were beyond compare. Concerning the present editor he would prefer to fall back upon the letter received from Prof. Huxley, in which he said:—"The influence for good of the spirit of sound criticism which permeates all the theological articles cannot be over-estimated; and in all other respects, so far as I can judge, the work is wonderfully well carried out." The toast was drunk with musical honours. Dr. Robertson Smith said it was hardly possible for him to thank them sufficiently for the way in which they had drunk his health. He would repeat how very much he had felt the constant kindness and support of all his contributors, without which a work of the kind was impossible. He feared that the editor must sometimes be more or less exacting in such cases. It certainly pained him more to be so than, according to his experience, it pained the contributor to meet the wishes that he expressed. Although all good English work had been due to the spirit of accommodation and of friendly help that pervaded our national life, from his own experience he did not think that any monument of English work had shown more of this good quality, which characterized literary men of every nationality, than had the "Encyclopædia Britannica." Prof. Newton proposed "The Publishers," and Mr. Adam W. Black responded. Mr. Sutherland Black gave "The Health of the Provost and Fellows of Christ's College," and with the reply of Dr. Peile the proceedings closed.

THE year 1889 being the fiftieth anniversary of the Royal Botanic Society, it is proposed that the occasion shall be celebrated by a special *fête*. An announcement on the subject will be made in due course.

PROF. JUDD informs us that he has communicated to the Geological Society a paper on the Tertiary volcanoes of the Highlands, dealing with some of the questions referred to in the article on this subject which appeared in NATURE two weeks ago.

ABOUT four years ago King Oscar of Sweden and Norway offered a prize, consisting of a gold medal valued at 1000 francs, and 2500 kr. (£140) in money, for any one great discovery within the sphere of higher mathematical analysis. The prize is to be awarded on His Majesty's sixtieth birthday, on January 21, 1889. Twelve papers have been sent in, seven of which are in French, four in German, and one in Italian.

VESUVIUS has lately been very active. It has been rapidly throwing up a new cone of eruption about 30 to 40 yards to the south-west of the original one, and the fissure across the crater plane towards the west-south-west is increasing in size and is richer in acid emanations. It is possible, therefore, that an eruption may take place soon on that side of the cone, since the vent tends to shift along the fissure pointing in that direction.

A SEVERE earthquake occurred in the Drant Valley on December 3 at 1.40 a.m. The shocks were from east to west, and were accompanied by subterranean noises.

IN addition to Prof. Milne's paper on the effects of earthquakes on the lower animals, to which we have already referred in these columns, the last number (vol. xii.) of the Transactions of the Seismologicul Society of Japan contains several other papers of interest, some of which, however, were noticed at the time they were read before the Society. Amongst other papers by Prof. Milne are: modern forms of pendulum seismometers; the Gray-Milne seismograph and other instruments in the Seismological Laboratory at the Imperial College of Engineering, Tokio; and on certain seismic phenomena demanding solution. A few of these latter are: sound-phenomena at the extremities of earthquakes; in soft ground the large horizontal motions are preceded by a series of vertical surface ripples; near to an origin the amplitude of normal motion is greater than the amplitude of transverse motion, but as the disturbance radiates they rapidly approximate to each other. Mr. W. G. Aston writes on earthquakes in Corea, giving a list of earthquakes prepared from the standard histories of that country, the "Tongkuk thong-kam" and the "Kuk-cho pong-kam," and showing that there were not more than twenty-seven earthquakes in all in that country in 1800 years. We observe also that the issue in Japanese of the Transactions of the Society is proceeding apace, and has now reached the fifth volume. This particular volume contains translations into Japanese of the following papers: earthquake effects, emotional and moral, by Prof. Milne; a model showing the motion of an earthquake particle during an earthquake, by S. Sekiya; earthquake frequency, by Dr. C. G. Knott.

ACCORDING to a private letter written by a resident at Godthaab, and sent to Denmark by the steamer *Fox*, Nansen encountered nothing but land covered with ice and snow in the interior of Greenland. The members of the Expedition, the writer says, were often able to "sail" along the smooth snowy surface on the *ski*. *Apropos* of the return of the Expedition, the first vessel leaving for Greenland next spring is the steamer *Hvielbjörnen*, belonging to the Greenland Company of Commerce. It departs late in March, so that the Expedition is due in Copenhagen at the end of May. A national subscription is now being raised in Norway to defray the cost of the Expedition, estimated at about £1000, part of this sum only having been as yet contributed. Some sort of national recognition of Dr. Nansen's achievements is also contemplated.

ON November 27, about 9 p.m., a brilliant meteor was seen at Christiansand, in Norway. It went from east to west in the southern sky, emitting a bright white light, finally bursting without any report.

FOGS of great density have prevailed recently in London, and have frequently spread over almost the whole of Great Britain and France. "It will probably not have escaped notice by those residing in the suburbs," says the *Times*, "that on many occasions lately, while the fog has lasted, moisture has poured down from the leafless branches of the trees as though they had

been exposed to a fall of rain, and the various hygrometers have shown the air to be completely saturated with moisture. Under such circumstances the fogs in London are always less injurious to life than those of a drier nature, and it will be observed that we have had no reports this year of cattle being suffocated at the Cattle Show by London fog, as they were a few years ago. What the difference may be between the two conditions would be an interesting subject for inquiry. On both occasions the fogs were anticyclonic, and it cannot be said that the number of fires in London has decreased during the past ten years."

THE Report on the Administration of the Meteorological Department of the Government of India in 1887-88, which has just been published, is divided into two parts. The first deals with the more important administrative questions that have arisen during the year; the second describes the actual working of the Department, and the condition of the observatories; it contains also extracts from the reports of the inspection of the stations. These reports show that in many cases the paid observers take but little interest in their work. Mr. Eliot has introduced various changes, among the chief of which are: (1) the discontinuance of solar and terrestrial radiation observations, except at a few selected stations, on the ground that these observations are open to various objections, and that the instruments are unsuited for exact measurement,—two instruments, apparently identical in construction, frequently giving different readings under the same circumstances; (2) the tabulation of all observations in a form admitting of easy reference, and of the calculation of daily averages,—at present, although the monthly means have been obtained, the average conditions of each day or week are not yet known; (3) the extension and improvement of the methods of collecting rainfall statistics. Rainfall is registered at all the meteorological stations, but each province has established its own method of taking the observations, the result being an utter want of uniformity in the hours of measurement, the times varying from sunrise to midnight. An observatory has been opened at Bagdad; and the question of the establishment of one at Perim, at the entrance of the Red Sea, is under consideration, at the suggestion of the English Meteorological Council.

ON November 1, a bird very rare in Europe was shot in the Island of Möen, in Denmark, viz. a specimen of the "isabel-coloured runner" (*Cursorius isabellinus*). The home of this bird is the Desert of Sahara. Only one or two specimens have hitherto been seen in Europe.

WE notice in the *Izvestia* of the East Siberian branch of the Russian Geographical Society, a very interesting paper by M. Khangaloff, on the customs of the Buriates some three or four centuries ago, when they did not yet carry on agriculture, and lived only by hunting and cattle-breeding. The author's attention has been devoted chiefly to the *zegheteaba*, *i.e.* the periodical hunting by whole tribes gathering together from places as distant from one another as Verkholensk, Tunea, and Transbaikalia. Several hundreds, and sometimes thousands, of men gathered for these communal huntings, which lasted for forty days, and the author gives interesting details as to the customs in use on such occasions. They are still maintained, although only few tribes come together, and in order to keep up the old associations, fines have been imposed on those who do not assist at the huntings. Several "gentes" take part in the communal huntings, and must send one man out of each ten men of each "gens." The poor are freed from the obligation. The cleverness of the Buriates in killing wolves with their arrows, while riding at full speed, is really astonishing. The best archers kill a wolf at a distance of 100 yards.

THE Superintendent of the Anting Missionary Hospital, in a report on that institution, says that the Chinese believe that various animals, principally the hedgehog, weasel, fox, snake, and rat, take up their abode in man and control his fortunes. The reason given by the Chinese for the selection of these animals is that they have discovered the secret of long life possessing which every other good thing is certain to follow. One patient insists that a man inside him holds interminable conversations with him. A strong cathartic removes this delusion for a few days, but the intruder is certain to return at the end of that time. With regard to the insane in China, they have a pitiable lot there. A plea of insanity is of no avail in a trial for murder, and the culprit is decapitated just as if he were sane. Usually, however, insanity takes a very harmless shape: holding conversations with imaginary persons is the commonest form; refusing to eat or drink, and insisting on sitting continually in one place, are also common.

A REPORT from Hirschberg states that while a reservoir was being made a subterranean river was lately discovered in the Riesengebirge. It is 2 metres below the surface of the earth. The river is said to be, at one spot, 150 metres broad.

PROF. KIKUCHI has published the geometry for Japanese students upon which, as we stated some few months since, he has been engaged. The English equivalent of the title-page is, "A Text-book of Elementary Geometry, vol. i., Plane Geometry, Books i., ii., iii. (corresponding to the Books i., ii., iii., of the Association Geometry)." The work is brought out by the Educational Department of Japan.

PROF. MATTHIAS DUVAL, of the Paris Medical Faculty, has just published a quarto atlas of embryology. It contains forty double plates, with over five hundred figures, concerning the embryological evolution of the chick.

A NEW alkaloid has been isolated from the poisonous plant *Fritillaria imperialis*, a member of the order Liliaceæ, by Dr. Fragner, of Prague. All parts of this plant, and particularly the bulbs, have long been known to be violently poisonous; the action of the poisonous principle being very similar to that contained in the *Scilla maritima*, which is so much used in medicine. In order to investigate the nature of this noxious substance, a large number of the crushed bulbs were triturated with lime, and the mixture evaporated to complete dryness upon a water-bath. The residue was then repeatedly treated with hot chloroform, and the solution so obtained agitated with water acidified with tartaric acid. On the addition of sodium carbonate to the concentrated solution, the alkaloid itself was obtained in the form of a voluminous yellow precipitate. After removal of the mother-liquor as completely as possible by means of the filter-pump, the substance was dissolved in hot alcohol. From this solution in alcohol the alkaloid crystallized in short needles, which, after several recrystallizations were obtained perfectly colourless. The crystals are very sparingly soluble in water, but readily in ether, chloroform, and alcohol, imparting to these liquids an extremely bitter taste. They melt at 254° C., and furnish, on analysis, numbers pointing to the formula $C_{35}H_{60}NO_4$. Dr. Fragner, in consideration of its source, has endowed the new alkaloid with the name "imperialine." On allowing a solution of imperialine in alcohol saturated with hydrochloric acid gas to stand for a short time, large translucent crystals of the hydrochloride, $C_{35}H_{60}NO_4HCl$, separate out; this salt is very soluble in alcohol or water, and these solutions also possess the bitter taste. On the addition of ether to a mixture of platinum or gold chloride and the alcoholic solution of the hydrochloride, a yellow oil is obtained which eventually becomes semi-solid. If this pasty substance be dissolved in hot dilute hydrochloric acid and allowed to stand, the platinum or gold salt is obtained, the former in orange and the latter in yellow-coloured crystals. The platinum salt, on analysis, was found to possess the composition $2C_{35}H_{60}NO_4HCl + PtCl_4$, and the gold salt gave numbers agreeing with the formula $C_{35}H_{60}NO_4HCl + AuCl_3$.

Thus the new alkaloid has been thoroughly investigated, and its composition determined with tolerable certainty. It is a significant sign of the progress of the times that these poisonous principles of the vegetable kingdom are being gradually isolated, and their nature determined. Of the wonderful processes by which they are built up within the vegetable cells, we are as yet almost completely in the dark, and can only hope for light and knowledge from the persevering attempts of chemists to understand their constitution and to synthesize them.

THE additions to the Zoological Society's Gardens during the past week include a Hawk-Owl (*Surnia funerea*) from Russian Finland, presented by Lord Lilford, F.Z.S.; a Nankeen Kestrel (*Tinnunculus cenchroides*) from Australia, presented by Mr. A. J. Wilkins; eight Wild Geese (*Anser cinereus*), a White-fronted Goose (*Anser albifrons*), a Herring Gull (*Larus argentatus*), British, presented by Mr. E. S. Cameron; two Galeated Pentonyces (*Pelomedusa galeata*), six Robben Island Snakes (*Coronella phocarum*) from South Africa, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; three Black Tortoises (*Testudo carbonaria*) from South Brazil, presented by Mr. Leonard Cooper; five Moorish Geckos (*Tarentola mauritanica*) from the South of France, presented by Mr. J. C. Warburg; an Australian Cassowary (*Casuarius australis*) from Queensland, three Barbary Turtle Doves (*Turtur risorius*) from North Africa, a White Stork (*Ciconia alba*), European, deposited.

OUR ASTRONOMICAL COLUMN.

THE UNITED STATES NAVAL OBSERVATORY.—Captain R. L. Phythian, the Superintendent of the Naval Observatory, Washington, has just published his Report for the year ending June 30, 1888. The great 26 inch equatorial, which is in the charge of Prof. Asaph Hall, is in good order, and has been in constant use for micrometric measurement of the satellites of Saturn and Mars, and the regular list of double stars. The surfaces of both Saturn and Mars were constantly and carefully examined, and drawings made from time to time. In the case of the latter planet, the "canals" of Prof. Schiaparelli, though specially looked for, both during and after the opposition, could not be made out. The reduction and discussion of these observations are well advanced, in particular the computations with respect to the theory of Hyperion, which are now nearly ready for a complete discussion. The transit circle was dismounted and cleaned after April 4, 1888, and remounted in July, but notwithstanding this interruption 1970 observations were obtained with it from October 1, 1887, to October 14, 1888. The reductions are, however, in a backward state, the computing staff being too weak in number. The results for 1883 have been printed, and those for 1884 are in the press. The programme for future work includes the observation of the stars of the zones S. Decl. 14°–18° for the Astronomische Gesellschaft. The 9·6-inch equatorial has been chiefly used in the continued revision of Yarnall's Catalogue, and the observation of minor planets, comets, and of occultations.

The appendices to the Report contain the results of chronometer trials, and of the examination of sextants, binoculars, and other instruments, chiefly for naval use; the report of the Transit of Venus Commission, and that of Lieut. Winterhalter on his visit to Europe, in which he strongly urges the desirability of the Naval Observatory being empowered to join in the scheme of the Paris Astrophysical Congress of 1887 for charting the heavens by means of photography.

THE TOTAL SOLAR ECLIPSE OF JANUARY 1, 1889.—As the track of this eclipse passes through California, San Francisco, lying but a few miles south of the shadow line, it is probable that it will be watched by a number of persons who might make useful observations, and would gladly do so, if suitably directed. With a view of securing the services of such volunteers, and of employing them to the best advantage, Prof. Holden has published a little pamphlet containing "suggestions for observers." The two principal points on which he lays stress are the determination of the exact limits of the shadow, by noting the duration of totality at places just within it, and the photographing of the corona. The pamphlet is not in the least intended for trained astronomers, but will probably prove very useful for the purpose for which it has been written. No English astronomers are going out to observe the eclipse, but, should the weather prove favourable, it will be well watched by American observers, for a strong party from Mount Hamilton itself are to occupy a station immediately on the central line, and Mr. Chas. Burckhalter, of Chabot Observatory, has organized a party of twenty amateur photographers for the purpose of obtaining pictures of the corona. Messrs. George and Thomas Davidson also, sons of Prof. Davidson, of the U.S. Coast Survey, will photograph the corona at the elevated station of Winnemucca, whilst five observers from the Harvard College Observatory, under the direction of Mr. W. H. Pickering, are to take up a very full programme of photographic, photometric, and spectroscopic observations. Mr. C. H. Rockwell, also, of Tarrytown, N.Y., who was one of the Caroline Island party in 1883, will observe the eclipse.

COMETS FAYE AND BARNARD, OCTOBER 30.—The following ephemerides for Berlin midnight are in continuation of those given in NATURE for 1888 November 29 (p. 114):—

THE BRITISH ASSOCIATION AND LOCAL SCIENTIFIC SOCIETIES.

THE fourth Annual Conference of Delegates of Corresponding Societies was held during the Bath meeting of the Association, thirty-eight local Societies having nominated representatives. The following is an abstract of the Report which has recently been issued by the Corresponding Societies Committee :—

At the first meeting the chair was taken by Dr. John Evans, Treasurer R.S., the Corresponding Societies Committee being represented by General Pitt-Rivers, Sir Douglas Galton, Prof. Boyd Dawkins, Prof. T. G. Bonney, Mr. W. Whitaker, Mr. G. J. Symons, Mr. W. Topley, Dr. Garson, Mr. J. Hopkinson, Mr. W. White, and Prof. R. Meldola, Secretary.

The delegates were invited to make any statements respecting the work done by the Committees appointed last year, or in connection with other subjects referred to in the Report which had been presented to the General Committee.

A discussion took place with reference to the working of the Ancient Monuments Act, in which the Deemster Gill, Prof. Boyd Dawkins, Dr. Evans, General Pitt-Rivers, Sir John Lubbock, and many of the delegates took part. The issue of greatest importance, so far as concerns the local Societies, is that these bodies should take upon themselves the responsibility of protecting, as far as possible, the ancient remains in their own districts.

Earth Tremors Committee.—Prof. Lebour reported that the Committee was about to apply for reappointment, with the object of, in the first place, prosecuting inquiries as to the best form of instruments, and the best conditions with respect to locality, foundation, &c., for fixing up such instruments. Several Societies and individuals had expressed their willingness to co-operate as soon as these conditions had been determined, and the Birmingham Philosophical Society had made a grant towards the expenses of these preliminary trials.

Prof. Lebour stated also that the North of England Institute of Mining and Mechanical Engineers had recently appointed a Committee, armed with a substantial grant, to make a series of experiments on so-called "flameless explosives." This Committee was now at work, and would gladly receive assistance in any way from kindred Societies. The same Institute had joined with the Mining Institutes of South Wales and Scotland in forming another Committee to conduct a series of experiments on fan-ventilation. He thought that these were examples of the kind of co-operation which the Conference of Delegates of Corresponding Societies was likely to bring about.

At the second meeting of the Conference, the chair was first taken by the Secretary, Prof. R. Meldola, and afterwards by the Vice-Chairman, Mr. W. Whitaker, the Committee being further represented by Mr. J. Hopkinson and Mr. W. White, and towards the close of the meeting by Dr. Evans, who had been detained at the Committee of Recommendations.

The Chairman, in opening the proceedings, said that it would be best to adopt their usual plan, and consider the suggestions and recommendations from the different Sections in their proper sequence.

SECTION A.

Temperature Variation in Lakes, Rivers, and Estuaries.—Dr. Mill said that he wished to point out some of the results that had been obtained by the Committee appointed to make the investigations in conjunction with the local Societies represented in the Association. He had a diagram which showed the work done more precisely than he could explain in a short time. The Committee had twenty observers working at various rivers; most of these rivers were in Scotland, only one or two being in England, while no observations had been started in Ireland. Their investigations showed that while in some rivers, particularly the Aray, the temperature was increased by rainfall, in others this condition was reversed, the temperature being found to suddenly fall during rain. He wished to impress upon the delegates the advisability of extending their observations throughout Scotland and England, and also of extending them to Ireland. Prof. Fitzgerald, the President of Section A, who was a member of the Committee, took a great interest in the subject, and had expressed an opinion that Mr. Symons's rain-gauge observers might make personal observations. Dr. Mill advised all observers to use the thermometer which he exhibited, and which he said was durable and cheap. He trusted that delegates on returning home would lay the subject before their Societies, give them some idea of the work of the Committee, and induce them to co-operate and make observations in their respective localities. Circulars, he added, would be sent to the Societies and to Mr. Symons's rain-gauge observers, and it was hoped that this would bring the question well before them. It would give local Societies an opportunity of doing what they professed to do, and he was perfectly certain they were anxious to promote real scientific work. The observations could be made with very little training, and the investigations of conscientious observers would lead to interesting results, as they would be considered by the Committee in connection with the temperature and rainfall of the districts in which they were made.

In reply to questions by Mr. Cushing and the Rev. E. P. Knubley, Dr. Mill said that the thermometer readings were taken at a depth of 6 inches below the surface of the water, and that the fullest particulars would be supplied by the Committee to any Society wishing to take part in the observations.

SECTION C.

Prof. Lebour, who had been nominated as the representative of the Committee of this Section, said that the Committees on (1) Sea-coast Erosion, (2) Underground Waters, (3) Erratic Blocks, and (4) Earth Tremors, the working of which had been explained to the delegates on former occasions, had been recommended for reappointment.

Geological Photography.—Prof. Lebour further informed the delegates that, in consequence of a paper read before Section C by Mr. O. W. Jeffs on local geological photographs, it was proposed by the Committee of the Section that a Committee should be appointed to collect and register such photographs. The proposal at present was so indefinite that there was no chance of the Committee of Recommendations dealing with it this year, but they gave the suggestion their cordial sympathy, and it was formally passed on to the meeting of delegates. It was hoped that delegates of Corresponding Societies, by discussing the matter among themselves, would have it so organized and ready to place before the Committee of the Section next year, and ultimately before the Committee of Recommendations, in such a form that a Committee of the Association might be appointed, with a small grant, to work the scheme satisfactorily. It was thought by the Committee of the Section that too many restrictions as to the uniformity of the photographs should not be enforced in the early stages of the scheme. The simple collection and registration of photographs was all that was at present aimed at.

The following suggestions with reference to this subject were forwarded by the Committee of the Section to the Secretary of the Conference :—

"(1) That a Committee be formed, having representatives for each county, charged with the arrangement of a local photographic survey for geological purposes in each district.

"(2) The Committee will gather together—

"(*a*) Names of Societies and individuals who have already assisted in this object, or who are willing to do so;

"(*b*) Copies of geological photographs already taken;

"(*c*) List of localities, sections of rocks, boulders, and other features desirable to be photographed;

and will arrange with local Societies for the work to be done as may be convenient or possible.

"(3) Each photograph to be accompanied by the following particulars :—

"(*a*) Name and position of locality or section;[1]

"(*b*) Details of features shown (with illustrative diagram or sketch whenever necessary for such explanation);

"(*c*) Scale of height and length, or figure introduced to indicate size in Nature;

"(*d*) Name of photographer and Society under whose direction the view is taken;

"(*e*) Date when photographed.

"(4) Size of photograph recommended: 12 × 10 inches (whole plate), but this is not compulsory.

"(5) Original negative to be the property of the Society or individual under whose direction it is taken, and who shall also fix a price at which copies may be sold.

"(6) One copy of each photograph to be the property of the British Association, and one other copy to be given to the Geological Society of London.

[1] Including Compass Direction.—*Sec. Corr. Soc. Comm.*

"(7) Each photograph officially received to be numbered and recorded in a reference-book, and a list published and circulated showing price at which members and others may purchase them.

"(8) A circular to be issued to all geological Societies, inviting their co-operation."

Mr. Jeffs said that a large number of Societies in different parts of the Kingdom had taken, from time to time, photographs of various geological sections and features as they came under their notice, but there had been no systematic way adopted either of collecting the photographs or of recording them, so that geologists interested might really know what had been taken. He thought that, if some arrangement could be made, a great deal of good might be done not only for the benefit of geological science, but also for educational purposes. Regarding regulations, he was not desirous of laying down any strict rules, but he thought that if the scheme were to be carried out at all satisfactorily, and at a minimum expenditure, some few regulations would be necessary.

Mr. Whitaker thought it a very fit subject for the Conference, and trusted that delegates would get their Societies to think it over. The object was to interest all the Societies, and to have a harmonious result.

Some further discussion took place with reference to the requirements of the proposed Committee and the mode of procedure in the field, in the course of which it was pointed out that the chief object was to secure photographs of typical and especially of *temporary* sections. The details of manipulation, the size of the photographs, method of mounting, registration of scale, &c., could only be settled when the Corresponding Societies had taken action in the matter, and the Committee had been formally appointed.

Section D.

The Committee of this Section was represented by Prof. Hillhouse.

Life-histories of Native Plants.—Prof. Meldola said that since their last meeting at Manchester, Prof. Bayley Balfour had received several applications for further particulars with reference to the suggestion which he communicated to last year's Conference. Prof. Balfour was unable to be present at Bath, but had forwarded the following:—

"*Suggestions for those studying the Life-histories of British Flowering Plants*:—

"(1) Seeds should be collected, and opportunity may be taken at the time of collection to note how they are disseminated in Nature—whether the fruit opens or not, whether they have appendages for promoting transport by animals or otherwise, whether they have colour or other features of attraction, &c.

"(2) The seeds being sown, their germination should be watched; its rapidity and manner noted. The variations and differences between albuminous and exalbuminous seeds are worthy of special note. The movements of the parts of the embryo in germination until it acquires its fixed position are also deserving of study. Further, the form of the parts of the embryo is various and instructive.

"(3) The development of the seedling into the adult can be readily watched in annuals and biennials, and smaller perennials. The succession of leaves after the cotyledons should be noted, and the forms which the leaves assume, and their positions and spread. The relative succession of buds in or adjacent to the axils of the later leaves and of the cotyledons should be observed, as also the ultimate fate of the buds developed. This will give a clue to the branching of the main axis of the plant, upon which its whole form and habit depend.

"(4) An important point to look at in the development is the amount, character, and position of any clothing of hairs the seedling may possess.

"(5) The development of the underground part of the seedling must not be neglected. The continuance of the primary root and its branching or its replacement by adventitious roots are points for particular attention, and also the formation upon it of any excrescence or buds. A sufficient number of seedlings must be grown to allow of proper study of these features.

"(6) The form of branching of the stem and leaves may be studied in the mature plant, which may be gathered wild. The formation of false axes should be specially looked for, and the complex relations often resulting from branching may be worked out upon the young top of a mature plant. It is not necessary to wait for the maturing of the seedling, but reference back to the seedling will show whether any observed relations are of late or early development in the life-history.

"(7) In the case of perennials, the mode of perennation is an interesting feature for observation, as well as the methods of vegetative propagation. In some cases the two processes are merged in one. Properly to understand perennation the perennating portions must be examined at all periods of the resting season as well as when they are starting anew into vegetative activity. Seedlings of perennating plants watched during two or three seasons will give a clue towards elucidation of the development.

"(8) When the seedlings begin to form flowers, the relation of the flower-shoots to the vegetative organs should be noted, and especially their sequence with reference to vegetative shoots. The succession of the flowers should be noted, as of course should be their structure and their adaptations to proper pollination. Many seedlings will not, of course, flower for years, and the sequence of flowers in such plants, and, indeed, in all cases, may be well traced in the mature plant growing wild.

"(9) After flowering and pollination the development of fruit must be studied. The parts concerned in forming fruit, the adaptations to scattering of the fruit or seed are points to be precisely noted.

"(10) The presence and position of any nectar-secreting structures outside as well as inside the flower are of much significance, and they should be carefully studied.

"(11) In connection with every point observed of structure and development the observer should ask himself, Why is this? What is this for? and endeavour to obtain some answer to the query.

"(12) A series of observations upon a specific plant made by a careful observer will enable him or her to draw up a complete history of its life, such as is hardly to be found recorded at the present day.

"I may add as a corollary that an interesting field for observation which local Societies might do good work in is that of the relation of plants to animals as food-plants. Some are discarded by browsing animals, others are preferred, and there are degrees of favouritism. Is there any principle of selection?"

Prof. F. O. Bower, the delegate from the Natural History Society of Glasgow, who was unable to be present at the meeting, forwarded a communication with reference to this subject, in which he pointed out that the chief precaution which would have to be observed in the carrying out of observations in accordance with Prof. Balfour's scheme, would be the correct identification of the species being worked upon.

Disappearances of Native Plants.—Prof. Hillhouse said that he was in charge of a Committee appointed two years ago for the purpose of collecting information as to the disappearance of native plants from their local habitats. Their report for 1887 said the Committee intended presenting a report in 1888 concerning its inquiries in Scotland. He came to that meeting prepared with a report, and learnt to his surprise that the Committee had lapsed, but an application had been made to the Committee of Section D to have it reappointed. He would give some brief account of their work in the past year. The report for Scotland covered eighty-five flowers which were extinct, or were "practically extinct," and they were of the most varied kinds. It had been discovered that *Nymphæa alba* (the white water-lily) had been almost exterminated in the lochs about Dumfries; the name of the person who had committed the ravages upon it was brought before the local Natural History Society, an appeal was made to the proprietors of the lochs, and the individual was warned off estates in the neighbourhood on pain of prosecution for trespass. There was one plant that had only a single station in Scotland, *Scheuchzeria palustris*, which was found in the Bog of Methven, and it had been destroyed in all probability by 300 or 400 black gulls settling in the bog and devouring everything in the shape of vegetation. Another plant which had been completely exterminated was one known as *Mertensia maritima*, which grew in shingle on the Bay of Nigg, and which had been destroyed by the shingle having been used to make concrete blocks to be used in the construction of a pier near at hand. Then a grass which grew in a patch near the Moray Frith had been destroyed by the overturning of a tree, which caused a large hole into which all the moisture of the patch drained; this grass was *Melica uniflora*. The Committee found that the disappearance of plants was caused in a great measure by the injudiciousness of individual botanists, and also by botanical exchanging clubs, who held out inducements

for the collection of eighty or a hundred specimens of extremely rare varieties. The Committee hoped to present a report next year.

At the conclusion of the Conference, votes of thanks were passed to the Chairman and Secretary.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—The Sheepshanks Astronomical Exhibition at Trinity College, open to the competition of any undergraduate of the University, has been awarded to Frank Watson Dyson and Gilbert Thomas Walker, brother scholars of the College, who are declared to be equal in merit. The value of the Exhibition is 50*l*. per annum, tenable for three years, and it will be divided between the successful candidates.

SCIENTIFIC SERIALS.

American Journal of Science, December.—The invisible solar and lunar spectrum, by S. P. Langley. This paper, which is an abstract of a memoir about to appear in the publications of the United States Academy of Sciences, summarizes the result of investigations carried on at the Allegheny Observatory in continuation of the author's previous researches on the infra-red of the solar spectrum to the extent of about three microns. By means of the improved apparatus here described, the extreme infra-red solar spectrum has now been searched from three to over eighteen microns; and it is shown that in this region the ratios between solar and lunar heat are completely changed from what they are in the visible spectrum. While the solar *light* in the latter is about 500,000 times that of moonlight, the solar heat received in the invisible part of the spectrum is probably less than 500 times the lunar. These studies also promise important results for meteorology, by opening to observation the hitherto unknown region of the spectrum, in which are to be found the nocturnal and diurnal radiations, not only from the moon towards the earth, but from the soil of the earth towards space.—A brief history of Taconic ideas, by James D. Dana. The Taconic question is here treated in chronological order from 1818 till the present year, in which the controversy may be regarded as practically closed. The conclusion is now firmly established that this system is not pre-Silurian, but merely another name for the older term "Lower Silurian."—Certain generic electrical relations of alloys of platinum, by C. Barus. In this paper are given the chief results of the investigations on the measurement of high temperatures already described in vol. xxxv. p. 407, of the *Journal*. The results generally point to a limit below which, in the case of solid metals and at ordinary temperatures, neither electrical conductivity nor temperature-coefficient can be reduced. It thus appears that a lower limit of both conductivity and temperature-coefficient is among the conditions of metallic conduction, not to say of the metallic state absolutely.—On the Puget group of Washington Territory, by Charles A. White. A careful study of some fossil Mollusca from the coal-bearing formation in the Puget Sound basin, shows that they belong to a hitherto unknown brackish-water fauna, characterizing a deposit of unusual interest. A section of this formation measured at the town of Wilkeson gives a minimum thickness of no less than 13,200 feet, with a probable maximum of 14,500 feet. The surprise caused by the discovery of such an extraordinary thickness in an estuary deposit is increased by the fact that its Molluscan fauna appears to range vertically throughout the whole formation. The fauna itself seems to be of the same age, but distinct from, the Laramie, which flourished, not in an estuary, but in a land-locked basin. The area of the Puget group includes the Cascade Range, but is not otherwise yet clearly defined eastwards from the Pacific seaboard.—Papers are contributed by L. G. Eakins, on some sulphantimonites from Colorado; by A. E. Kennelly, on the voltametric measurement of alternating Currents; by Dr. C. Hart Merriman, on the fauna of the Great Smoky Mountains, with description of a new species of red-backed mouse; by W. E. Hidden and J. B. Mackintosh, on anerlite, a new thorium mineral; and by O. C. Marsh, on a new family of horned Dinosaurians (*Ceratops montanus*) recently discovered *in situ* in the Laramie deposits of the Cretaceous period, in Montana This reptile was a very formidable animal, armed not only with horns of great strength, but with a thick dermal hide, and varying in length from 25 to 30 feet.

SOCIETIES AND ACADEMIES.

London.

Royal Society, December 6.—"Some Observations on the Amount of Light reflected and transmitted by certain kinds of Glass." By Sir John Conroy, Bart., M.A., Bedford Lecturer of Balliol College and Millard Lecturer of Trinity College, Oxford. Communicated by A. G. Vernon Harcourt, F.R.S.

Conclusions.—It seems probable that the amount of light reflected by freshly polished glass varies with the way in which it has been polished, and that, if a perfect surface could be obtained without altering the refractive index of the surface-layer, then the amount would be accurately given by Fresnel's formula, but that usually the amount differs from that given by the formula, being sometimes greater and sometimes less.

The formation of a film of lower refractive index on the glass would account for the defect in the reflected light; but to account for the excess, it seems necessary to assume that the polishing has increased the optical density of the surface-layer, and the changes produced in the amount of light transmitted and in the angle of polarization support this view.

After being polished, the surface of flint glass seems to alter somewhat readily, the amount of the reflected light decreasing, and the amount of the transmitted increasing, whilst with crown glass the change, if any, proceeds very slowly.

There is no evidence to show to what particular cause these changes are due.

The values of the transmission coefficients for light of mean refrangibility for the two particular kinds of glass are given, and show that for 1 cm. the loss by obstruction amounts to 2·62 per cent. with the crown glass and 1·15 per cent. with the flint glass.

Linnean Society, December 6.—Mr. W. Carruthers, F.R.S., President, in the chair.—Mr. W. H. Beeby exhibited and made some remarks on specimens of *Valeriana mikanii* and *sambucifolia*, and a series of *Potamogeton fluitans*.—Mr. F. W. Oliver described the nature and growth of leaf-emergences in *Eriospermum folioliferum*.—Mr. E. M. Holmes exhibited specimens of a new Assafœtida plant (*Ferula fœtidissima*), and a monstrosity of *Zea Mays*.—Mr. J. G. Baker exhibited a curious variety of *Vicia sepium*, found in North Yorkshire.—Mr. T. Christy exhibited specimens of an undetermined species of *Echium* received from Persia, and employed medicinally as a good alterative.—The first paper read was one by Dr. Costerus on malformation in *Fuchsia globosa*, upon which Prof. Bower offered some critical remarks.—The next paper was by Mr. B. T. Lowne, who gave an admirable demonstration of the mode of development of the egg and blastoderm of the blow-fly. His conclusions were criticized by Prof. Stewart, Prof. Howes, and Mr. A. R. Hammond.—In continuation of the Reports on the collections made by Mr. Ridley in Fernando Noronha, a paper was read on behalf of Mr. Boulenger, enumerating the fishes and reptiles which had been identified by him.

Physical Society, December 8.—Prof. Reinold, F.R.S., President, in the chair.—The following communications were read:—Note on a modification of the ordinary method of determining electro-magnetic capacity, by Dr. J. W. W. Waghorne.—On some facts connected with the systems of scientific units of measurement, by Mr. T. H. Blakesley.—Some improved polarizing apparatus for microscopes were exhibited and described by Dr. S. P. Thompson. For polarizer, he uses an Ahrens' prism, and for analyzer a flat-ended one of his own design. The Ahrens' prism is formed from a rectangular block of spar, two faces of which are perpendicular to the optic axis; two cuts parallel to the axis are made from the middle of one side to the ends of the opposite, and the cut faces are polished and cemented by Canada balsam. A short prism with wide angle is thus obtained, which can be readily fitted to the substage of the microscope. The analyzer, which consists of two wedges of spar, is mounted in a tube which fits on the eye-piece, and by recognizing that the upper end need not be larger than the pupil of the eye, the author has been able to considerably reduce the length of the prism, and still keep the bottom end large enough to collect all the rays passing through the eye-piece. Several ingenious methods of cutting spar so as to produce prisms with minimum waste were described and illustrated by models, and a "Nicol" made by the inventor at the age of 79 was exhibited. Mr. Lant Carpenter asked the author why he condemned analyzers placed directly behind the objective, for in

his experience this arrangement gave the most satisfactory results. In reply, Dr. Thompson said his experience was decidedly different from that of Mr. Lant Carpenter, and mentioned that Zeiss had abandoned the common arrangement, and now introduced his analyzers between the two lenses of his Huyghenian eye-pieces.

Chemical Society, December 6.—Mr. W. Crookes, F.R.S., President, in the chair.—The following papers were read :—A method of determining vapour-density, applicable at all temperatures and pressures, by Dr. W. Bott. The apparatus consists of a large Victor Meyer's bulb, carrying a detachable head-piece, which can be connected with the air-pump. The neck of the bulb communicates with a mercury pressure-gauge, which again is connected with a wide measuring tube attached to an adjustable mercury reservoir. The experiment is conducted as follows. The substance having been placed in the head-piece of the vessel, the latter is heated until the volume has become constant. The apparatus is then exhausted as far as may be requisite, and the reservoir so adjusted that the graduated measuring tube is filled with mercury. The pressure indicated by the gauge having been carefully noted, the substance is allowed to drop into the hot part of the vessel, and the surplus pressure produced by its evaporation is removed by drawing off an equivalent volume of air into the measuring tube until the initial pressure in the gauge has been restored. From the volume of gas measured in the graduated tube, the density referred to hydrogen is obtained by the formula $d = 8484893 \frac{S(1 + 0\cdot00367t)}{VP}$; in which S = weight of substance, V = volume of gas in measuring tube, P = pressure of gas in measuring tube, t = temperature of gas. In the discussion which followed, Prof. Ramsay, remarking on a statement made by the author that he proposed to make use of the apparatus in studying the influence of pressure on dissociation, said that recent investigations had shown that the Victor Meyer form of apparatus was by no means a suitable one for the study of such problems ; and he expressed the opinion that for this reason results such as those recently published by Nilson and Petterssen could not be accepted as final.—Some derivatives and new colouring-matters of α-pyrocresole, by Dr. W. Bott and Mr. J. B. Miller. The authors have prepared di- and tetranitro- and di- and tetramido- derivatives of α-pyrocresole oxide. Both amido-derivatives can be diazotized, and the diazo-salts interact with β-naphthol in alkaline solution, yielding two oxyazo-compounds ; these are insoluble in water, but can be converted into soluble sulphonic acids, which dye silk and wool maroon and salmon colour respectively.—Berberine, by Prof. W. H. Perkin. When oxidized with excess of potassium permanganate in slightly alkaline solution, berberine yields, as principal product, hemipinic acid, $C_{10}H_{10}O_6$, as Schmidt and Schilbach (*Arch. Pharm.* [3], 164–170) have already shown. In view of the interesting results lately obtained by Goldschmiedt in his examination of hemipinic and methemipinic acids, the author has carefully re-examined the hemipinic acid from berberine, and is convinced that it is identical with that obtained by the oxidation of narcotine. The acid from berberine contains two (OCH_3) groups : on fusion with potash it yields protocatechuic acid ; and on distilling it with ethylamine, hemipinethylimide, melting at 96°, is formed. This latter substance possesses all the properties of the hemipinethylimide obtained by Liebermann by the action of ethyl iodide on the potassium salt of hemipinimide (from narcotine), and thus the identity of the two hemipinic acids from berberbine and narcotine is proved. Oxidation with a limited quantity of permanganate results in the production of a number of new substances, three of which have been obtained in a state of purity : a new acid, $C_{20}H_{17}NO_9$ (m.p. = 143°), and two neutral substances, $C_{20}H_{17}NO_8$ (m.p. = 236°) and $C_{20}H_{15}NO_7$ (m.p. = 150°), all of which yield protocatechuic acid on fusion with potash. Employing Zeisel's method, the author finds that two methoxyl (OCH_3) groups are present in the berberine molecule.—The action of ammonia on some tungsten compounds, by Dr. S. Rideal.—Condensations of α-diketones with ethylic acetoacetate, by Dr. F. R. Japp, F.R.S., and Dr. F. Klingemann. A preliminary note on the reactions of ethylic phenanthroxylene-acetoacetate, the condensation compound of phenanthraquinone with ethylic acetoacetate.—Thionyl thiocyanate, by Mr. G. C. McMurtry.—Mercuric chlorothiocyanate, by the same.—The action of chromium oxychloride on pinene, by Messrs. G. G. Henderson and R. W. Smith.—Tectoquinone, by Dr. R. Romanis. A continuation of the author's work on the quinone-like compound, $C_{18}H_{16}O_2$, found in teak resin (*Tectonia grandis*), and also in the products of the destructive distillation of the wood. Tectoquinone crystallizes in oblique rhombic prisms of an amber colour, resembling sulphur, melts at 171°, and is a very stable substance, dissolving in nitric and sulphuric acids without change. On reduction it yields a hydrocarbon, $C_{18}H_{22}$, and it is suggested that it may be the hitherto unknown retenequinone.—The decomposition of nitroethane by alkalies, by Prof. W. R. Dunstan and Mr. T. S. Dymond. Nitroethane in contact with potassium carbonate or its aqueous solution readily yields potassium nitrite and an oily liquid having the formula C_6H_9NO, which boils at about 170°, decomposing at a somewhat higher temperature with the formation of what appears to be a pyridine derivative.

Zoological Society, November 20.—Prof. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the months of June, July, August, September, and October, 1888, and called attention to the acquisition of three specimens of Pallas's Sand-Grouse (*Syrrhaptes paradoxus*), captured out of the many flocks of this Asiatic bird that have lately visited the British Islands.—A letter was read from Prof. J. B. Steere, giving a preliminary account of the "Tamaron," a bovine animal found in the Island of Mindoro, Philippines, which he believed to be allied to the Anoa of Celebes.—Mr. Edgar Thurston exhibited and made remarks upon a collection of Corals from the Gulf of Manar, Madras Presidency.—Mr. H. Seebohm exhibited and made remarks on a specimen of a new species of Pheasant (*Phasianus tarimensis*), obtained by General Prjevalsky at Lob Nor, Central Asia.—Mr. H. Seebohm also exhibited a specimen of a species of Plover new to the British Islands (*Vanellus gregarius*), which had been shot in Lancashire about twenty-five years ago, and had been previously supposed to be a Cream-coloured Courser.—Mr. J. W. Hulke, F.R.S., read a paper on the skeletal anatomy of the Mesosuchian Crocodiles, based on fossil remains from the clays near Peterborough, in the collection of Mr. A. Leids, of Eyebury.—Mr. Oldfield Thomas read a paper on a collection of small Mammals obtained by Mr. William Taylor in Duval County, South Texas. The collection contained examples of one new species and one new geographical variety, besides adding no less than six species to the national collection of Mammalia.—A communication was read from M. L. Taczanowski, containing a supplementary list of the birds collected in Corea by Mr. Jean Kalinowski.

December 4.—Prof. Flower, F.R.S., President, in the chair.—Mr. Howard Saunders exhibited and made remarks on an adult male of the American Green-winged Teal (*Querquedula carolinensis*), shot in Devonshire in 1879.—Mr. Oldfield Thomas gave an account of the Mammals obtained by Mr. C. M. Woodford during his second expedition to the Solomon Islands. The author stated that the total number of species of Mammals now known from the Solomons was brought up by the present collection from 13 to 22, and that of these no less than 8 had been discovered by Mr. Woodford, his previous collection having contained examples of 2 and the present of 6 new species. There were also two new genera of Bats to be added to the one previously described.—Mr. F. E. Beddard read a paper upon the genus *Clitellio*, which had been recently investigated by him at the Marine Biological Station at Plymouth.—Prof. Howes and Mr. Davies read a paper on the distribution and morphology of the supernumerary phalanges in the Anurous Batrachians.—A communication was read from Mr. J. J. Lister, giving a general account of the natural history of Christmas Island, in the Indian Ocean, which he had visited in 1887 as naturalist to H.M. surveying-vessel *Egeria*.—Mr. Oldfield Thomas read a paper on the Mammals of Christmas Island, obtained by Mr. Lister during the same expedition.—This was followed by reports on the Reptiles of Christmas Island obtained during the expedition, by Mr. G. Boulenger ; on the Terrestrial Mollusks, by Mr. Edgar A. Smith, on the Coleoptera, by Mr. C. J. Gahan ; on the Lepidoptera, by Mr. A. G. Butler ; on the other Insects, by Mr. Kirby ; and on the Annelida, Myriapoda, and Land Crustacea, by Mr. R. I. Pocock.

Entomological Society, December 5.—Dr. D. Sharp, President, in the chair.—Mr. W. F. Kirby exhibited, for the Rev. Dr. Walker, a variety of the female of *Ornithoptera brookiana* ; also, for Major Partridge, an undetermined species of the genus *Hadena*, captured last summer in the Isle of Portland.—Mr. R. South exhibited a series of *Tortrix piceana*, L.,

from a pine wood in Surrey; also melanic forms of *Tortrix podana*, S.—Prof. Meldola, F.R.S., exhibited, for Dr. Laver, a melanic specimen of *Catocala nupta*, taken last September at Colchester.—Mr. E. B. Poulton exhibited preserved larvæ of *Sphinx convolvuli*, showing the extreme dark and light forms of the species.—Mr. McLachlan, F.R.S., called attention to a plate, representing species of the genus *Agrotis*, executed by photography, illustrating a memoir by Dr. Max Standfuss, in the *Correspondenz-Blatt*, Verein *Iris*, in Dresden, 1888. He considered it was the best example of photography as adapted for entomological purposes he had ever seen.—The Rev. Canon Fowler exhibited a specimen of *Mycterus curculionides*, L., sent to him by Mr. Olliff, and taken near Oxford about 1882.—Mr. W. Nicholson exhibited several melanic varieties of *Argynnis niobe* and *A. pales*, collected by himself last summer in the Engadine.—Mr. J. H. Leech exhibited a collection of Lepidoptera formed last year at Kiukiang. It included several new species.—Mr. H. Goss exhibited, for the Rev. T. A. Marshall, fifteen undescribed species of British *Braconidæ*.—M. A. Wailly exhibited a collection of Lepidoptera lately received from Assam, containing upwards of thirty-five species of *Papilio*, *Ornithoptera*, *Charaxes*, *Diadema*, *Cyrestis*, and other genera.—Mr. Meyer-Darcis exhibited specimens of *Sternocera tricolor*, Kerr, and *S. variabilis*, Kerr, from Lake Tanganyika; and two new species of *Julodis* from Syria.—Mr. F. Merrifield exhibited, and made remarks on, a long series of *Selenia illustraria*, *S. illunaria*, and *E. alniaria*, in illustration of his paper on "Pedigree Moth-breeding."—Lord Walsingham, F.R.S., exhibited, and made remarks on, a series of species representing the genera *Snellenia*, Wlsm., *Œdematopoda*, Z., and *Eretmocera*, Z.—The Rev. T. A. Marshall communicated a paper entitled "A Monograph of British *Braconidæ*, Part III."—The Rev. Dr. Walker communicated a paper entitled "Description of a variety of the female of *Ornithoptera brookiana*."—Lord Walsingham read a paper entitled "A Monograph of the genera connecting *Tinægeria*, Wlk., with *Eretmocera*, Z." A discussion ensued, in which Mr. Stainton, F.R.S., and Dr. Sharp took part.—Mr. Merrifield read a paper entitled "Incidental Observations in Pedigree Moth-breeding." This paper contained a detailed account of experiments with *Selenia illustraria*, *S. illunaria*, and *E. alniaria*, which, so far as they had yet proceeded, indicated that retardation of development in the growing stages of the larvæ, as well as in the pupal stage, was the cause of the darkening of colour in the perfect insects; and that a low temperature had the effect of causing such retardation. Lord Walsingham, Mr. Poulton, Prof. Meldola, Mr. White, and Mr. Merrifield took part in the discussion which ensued.—Mr. J. H. Leech read a paper entitled "Description of a small collection of Lepidoptera from Kiukiang." Captain Elwes said he had examined this collection with very great interest, and was struck with the similarity of many of the species to those from Sikkim.

Geological Society, December 5.—Dr. W. T. Blanford, F.R.S., President, in the chair.—The following communications were read:—Notes on two traverses of the crystalline rocks of the Alps, by Prof. T. G. Bonney, F.R.S. These journeys were undertaken in the summer of 1887, in the company of the Rev. E. Hill, in order to ascertain whether the apparent stratigraphical succession among the gneisses and crystalline schists which the author had observed in the more central region of the Alps, held good also in the Western and Eastern Alps. At the same time all circumstances which seemed to throw any light on the origin of the schists were carefully noted. The author examined the rocks along two lines of section:—(1) By the road of the Col du Lautaret from Grenoble to Briançon, and thence by the Mont Genèvre and the Col de Sestrières to Pinerolo, on the margin of the plain of Piedmont. (2) From Lienz, on the upper waters of the Drave, to Kitzbuhel; besides examining other parts of the central range, east of the Brenner Pass. The specimens collected have subsequently been examined microscopically. The results of the author's investigation may be briefly summarized as follows:—(1) While rocks of igneous origin occur at all horizons among the crystalline series of the Alps, these, as a rule, can be distinguished; or, at any rate, even if the crystalline schists in some cases are only modified igneous rocks, these are associated with recognizable igneous rocks of later date. (2) There are, speaking in general terms, three great rock-groups in the Alps which simulate curiously, if they do not indicate, stratigraphical sequence. The lowest and oldest resembles the gneisses of the Laurentian series; the next, those rather "friable" gneisses and schists called by Dr. Sterry Hunt the Montalban series; the third and uppermost is a great group of schists, generally rather fine-grained, micaceous, chloritic, epidotic, calcareous, and quartzose, passing occasionally into crystalline limestones, and (more rarely) into schistose quartzites. (3) The Pietra Verde group of Dr. Sterry Hunt, so far as the author has been able to ascertain, consists mainly of modified igneous rocks, of indeterminable date, and is at most only of local, if, indeed, it be of any classificatory value. (4) Of the above three groups the uppermost has an immense development in the Italian Alps and in the Tyrol, north and south of the central range. It can, in fact, be traced, apparently at the top of the crystalline succession, from one end of the Alpine chain to the other. (5) The middle group is not seldom either imperfectly developed or even wanting, appearing as if cut out by denudation. It was not seen in the traverse of the Franco-Italian Alps, except perhaps for a comparatively short distance on the eastern side, being probably concealed by Palæozoic and Mesozoic rocks on the western side. It is not very completely developed in the Eastern Tyrol, and seems to prevail especially in the Lepontine Alps, and on the southern side of the watershed. (6) The lowest group is fairly well exposed, both in the French Alps and in the Central Tyrol. (7) As a rule, the schists of the uppermost group had a sedimentary origin. The schists and gneisses of the middle group very probably, in part at least, had a similar origin. In regard to the lowest group it is difficult, in the present state of our knowledge, to come to any conclusion. (8) The slates and other rocks of clastic origin in the Alps, whether of Mesozoic or of Palæozoic age, though somewhat modified by pressure, are totally distinct from the true schists above mentioned, and it is only under very exceptional circumstances, and in very restricted areas, that there is the slightest difficulty in distinguishing between them. The evidence of the coarser fragmental material in these Palæozoic and later rocks indicates that the gneisses and crystalline schists of the Alps are very much more ancient than even the oldest of them. (9) The remarks made by the author in his Presidential address, 1886, as to the existence of a "cleavage-foliation" due to pressure, and a "stratification-foliation" of earlier date, which seemingly is the result of an original bedding, and as to the importance of distinguishing these structures (generally not a difficult thing), have been most fully confirmed. He is convinced that many of the contradictory statements and much of the confusion in regard to the origin and significance of foliation are due to the failure to recognize the distinctness of these two structures. In regard to them it may be admitted that sometimes "extremes meet," and a crystalline rock pulverized *in situ* is very difficult to separate from a greatly squeezed fine-grained sediment; but he believes these difficulties to be very local, probably only of a temporary character, and of little value for inductive purposes. After the reading of this paper, the author's conclusions were discussed by the President, Mr. Teall, Dr. Hicks, Mr. Bauerman, Prof. Blake, and Dr. Geikie.—On fulgurites from Monte Viso, by Frank Rutley.—On the occurrence of a new form of tachylyte in association with the gabbro of Carrock Fell, in the Lake District, by T. T. Groom. Communicated by Prof. T. McKenny Hughes.

PARIS.

Academy of Sciences, December 10.—M. Daubrée in the chair.—Observations of Faye's comet, made at the Marseilles Observatory, with the 0·80 m. Foucault telescope, by M. Stephan. These observations cover the period from December 5-8, when the nucleus was equal to a star of the eleventh or twelfth magnitude.—Geographical work in Brazil, by M. L. Cruls. The Imperial Observatory of Rio de Janeiro having undertaken to determine the geographical positions of a number of stations on the railway between the capital and Sabara, the results are given for the first two stations of Rodeio and Entre-Rios.—On the application of the theta functions of a single argument to the problems of rotation, by M. F. Caspary. A *résumé* is given of the calculations which the author has worked out with a view to determining the formulas relative to the problem of rotation of a heavy body suspended at a point of its axis.—On a general proposition regarding linear equations with partial derivatives of the second order, by M. Emile Picard.—On the employment of oxygenated water for the quantitative analysis of the metals of the iron group: (1) chromium, by M. Adolphe Carnot. On the solutions of various metals of the iron group oxygenated water determines certain reactions, sometimes of a reducing, sometimes of an oxidating, character. This property is capable of being

turned to account in chemical analysis, and the author proposes to deal successively with chromium, manganese, iron, cobalt, and nickel. In the present paper he shows the remarkable reaction furnished by chromic acid with oxygenated water, known as the Barreswil reaction.—On a latex of *Bassia latifolia*, Roxb., by MM. Edouard Heckel and Fr. Schlagdenhauffen. This plant, the well-known *Mohwa* of British India, is found to yield by incision a latex capable of supplying a kind of gutta-percha. When evaporated to about one-fourth of its volume, the sap furnishes an adhesive mass in the proportion of 6·67 per cent., which is partly soluble in alcohol and acetone, and which in the insoluble state leaves 27·027 per cent. of a gutta, the composition and industrial properties of which will form the subject of a future memoir.—On some new or little-known Infusoria, by M. J. Kunstler. Several minute intestinal parasites of various animals are described, including a remarkable ciliated Infusorium peculiar to *Periplaneta americana*.—On the *coussinet* (*cushion* or *pad*), a new organ attached to the sting of the Hymenoptera, by M. G. Carlet. This organ, here for the first time described, appears to be a sort of pivot round which the sting revolves, preventing this weapon from adhering to the teguments, and facilitating its movements. But the chief function of the "pad" is to retain in the sacs of the trachea the supply of air necessary for their inflation. This it effects by facilitating the action of the operculum, which thus appears to be a veritable safety-valve in the abdominal region.—On the measurement of the large bones in the human system, and on its applications to anthropological and medico-legal questions, by M. Etienne Rollet. The results are given of the measurements, made with Broca's apparatus, of the large bones of fifty men and fifty women lately deceased in the hospitals of Lyons. Much asymmetry was discovered between the bones on the right and left sides of the skeleton. An attempt made to determine stature from the size especially of the femur and humerus yielded satisfactory results. Compared with those of negroes and negresses, these measurements show generally that in the black race the upper and lower members, especially tibia and radius, are longer than in the South European, the difference being more marked in the female than in the male sex.—On the phosphated deposits of Montay and Forest, Département du Nord, by M. J. Ladrière. The author describes the origin and composition of these deposits, which in some places are rich enough to be worked with profit.—The dislocations of the primitive formations in the north of the central plateau of France, by M. L. de Launay. The lacustrine and independent origin of the various coal basins in this region is generally admitted by modern geologists. Here the author goes further, and endeavours to determine the causes to which was due the creation of the pre-Carboniferous lakes themselves, as well as their actual position on the plateau. This study is largely based on an entirely new and minute examination of the foldings to which the gneisses and mica-schists of the underlying systems have been subjected. The history of these movements, comprising a considerable number of progressive phases, shows that the successive dislocations invariably took place in the same direction, each great disturbance being merely an intensified repetition of the preceding. The general result in this region was to connect in one vast V-shaped system the Breton and Morvan foldings running respectively in the directions from north-east to south-east and from north-east to south-west.

AMSTERDAM.

Royal Academy of Sciences, November 24.—M. Hugo de Vries read a paper on the pangenesis of Darwin, expressing the conviction that Darwin's doctrine presents a great many more data for the explanation of various phenomena in the domain of heredity than the doctrine of Weismann. The author especially tried to demonstrate that the hypothesis of the transport of gemmules may be rejected without endangering the validity of the arguments implicated in that hypothesis, which would connect the separate properties of any organism with some definite species of particles of living matter. He also pointed to the fact that the theory expounded after Darwin's time, according to which the nucleus of the germ-cell must be the seat of heredity, is in accordance with the import of the last-mentioned hypothesis.—On tænodal points, by M. Korteweg. The author treated of their first appearance and disappearance on a gradually deformed surface. There exist four kinds of singular points of the first order of exceptionality, where two or more tænodal points come together, viz. two quite different species of double tænodal points—oscular points and conical points. When a double tænodal point occurs on the variable surface, a couple of tænodal points pass from reality to non-reality, or *vice versâ*. An oscular point is not accompanied by any change in the number of real tænodal points. In a conical node, as many couples as there are real double lines (six at most) at the conical node of the cubic surface obtained by neglecting all terms of the fourth order and higher, become real or imaginary according to the direction of the deformation. The other couples (six at least) cannot emerge from non-reality. As an immediate result of his general theory, the author deduces the theorem: The difference between the number of real tænodal points and real lines is the same for every cubic surface, and equal to three.—M. Martin showed that the lower jaw, found in the year 1823 when digging the canal called "Luid-Willemsvaart," in the Kaberg, near Maestricht, and hitherto regarded as the remains of a so-called fossil or diluvial human being, was not found in the geological formation which harbours such remains, but in another of more recent date, so that the importance of this jaw—found by the author after a long and troublesome search in the anatomical cabinet of the Leyden University—can no longer be maintained. —M. Martin stated that he had discovered recently, in a parcel of petrifactions collected by the mining engineer, J. A. Hooze, in Martapoera, some characteristic fossils from the chalk-formation; so that it is positively ascertained that in the south-eastern part of Borneo there exists a chalk-formation, as was formerly supposed by Geinitz.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Seas and Skies in many Latitudes: Hon. Ralph Abercromby (Stanford).—The Region of the Eternal Fire, Popular Edition: C. Marvin (Allen).—The Floral King; a Life of Linnæus: A. Alberg (Allen).—The British Journal Photographic Almanac, 1889 (Greenwood).—Nature's Fairy-Land, 2nd edition: H. W. S. Worsley-Benison (E. Stock).—Hand-book to the Optical Lantern: Welford and Sturmey (Iliffe).—The Blowpipe in Chemistry, Mineralogy, and Geology, 2nd edition: Lieut.-Colonel W. A. Ross (Lockwood).—Round about New Zealand: E. W. Payton (Chapman and Hall).—Through the Heart of Asia, 2 vols.: G. Bonvalot (Chapman and Hall).—Natural History Collections made in Alaska between the Years 1877 and 1881: E. W. Nelson (Washington).—Our Rarer Birds: C. Dixon (Bentley).—The Alps: Prof. F. Umlauft, translated by L. Brough (K. Paul).

CONTENTS.

THURSDAY, DECEMBER 27, 1888.

THE BUTTERFLIES OF THE EASTERN UNITED STATES AND CANADA.

The Butterflies of the Eastern United States and Canada, with Special Reference to New England. By Samuel H. Scudder. Part I. (Cambridge, Mass., U.S.A. : Published by the Author, 1888.)

THIS is perhaps the most remarkable work on butterflies which has ever been published; and though it has some features which cannot meet with universal approval, it will make a mark in entomological literature which cannot fail to influence future writings. It has, as the author tells us in his prospectus, been twenty years in preparation, of which eight have been entirely given up to it, and embodies thirty-five years of experience in the field, as well as an immense deal of literary research. The result is certainly a work of which, notwithstanding its defects, both the author and his countrymen may well be proud; and considering that it is published at the sole cost and risk of Mr. Scudder himself, who informs me that a sale of 350 copies is necessary before the cost of production can be repaid, it is to be hoped that scientific societies and entomologists in all parts of the world will support his arduous undertaking by subscribing to it The work is a large quarto, and will be completed in twelve monthly parts, each containing eight plates, coloured and plain, and about 144 pages of text. Of the plates, seventeen are to be devoted to butterflies, six to their eggs, eleven to caterpillars, two to the nests of caterpillars, three to chrysalides, two to parasites, thirty-three to structural details, nineteen will be maps and groups of maps, illustrating the geographical distribution of butterflies, and three are portraits of early American naturalists,—in all, about 2000 figures on ninety-six plates, together with over 1700 pages of letterpress. Considering that both letterpress and plates are of a high character—the chromolithographs by Sinclair and Son, of Philadelphia, being the best I have ever seen, and far superior in detail, fineness, and accuracy to many hand-coloured plates—and that the uncoloured plates are often of microscopical details which require the greatest care and accuracy, I do not think that the price, which is 5 dollars a part, or 50 dollars for the entire work if the whole is paid before January 1, 1889, is too high; though it will certainly place the book beyond the means of many who would wish to possess it. When complete, which will probably be in the course of the next year, the work will only be sold bound in three volumes at 75 dollars, so there is a decided advantage to early subscribers.

From the systematic list at the end of the first volume it appears that the number of species recognized as occurring in New England is about 124, to which 42 not found within these limits will be added in the appendix; so that the amount of space devoted to each species is very much larger than in any other work on butterflies with which I am acquainted. A great deal of the work, however, is taken up with detailed descriptions of the eggs, larvæ, chrysalides, and imagos, which seem to me to be of unnecessary length when accompanied by so many and such good figures. There are also full analytical tables of the families, genera, and species, based on the characters, not only of the imago, but also on those of the egg, larva, and chrysalis, which is a feature not attempted to anything like the same extent in any previous work; though I am somewhat doubtful whether its practical utility is in proportion to the labour it entails both on author and student. How far these tables will prove useful and correct when applied to species and genera not found in New England, and therefore not examined with the same care by the author, is another question; for it appears to be one of the gravest weaknesses of this work that it attempts to deal in a systematic way—far more minute than any which has hitherto been thought possible—with the species of a very limited fauna; apparently without sufficient consideration of the very much more numerous, and probably more variable, allied species and genera found in other parts of the world.

It has long been known that Mr. Scudder's views on nomenclature are peculiar to himself; and looking on nomenclature, as I do, as merely a means to an end, and of very minor importance provided the same names are used for the same objects by all naturalists, I regret deeply that the utility of such a work as this should be marred to some extent, by the fact that the generic names are in many cases used by no other American or European lepidopterist but Mr. Scudder himself. To such an extent does this peculiarity of nomenclature prevail, that out of seventy-six generic names used for 124 species of butterflies occurring in New England only twenty are in general use; nine or ten more are in partial use; and the remainder are mostly the fancies of Hübner—which have been practically ignored by recent systematists—or the creations of Mr. Scudder himself.

The specific names, however, are happily in most cases the same as those used by Edwards, Strecker, and other lepidopterists; and the English names, of which there is a pretty variety, may be used by those who are amused by them and do not wish to be understood by others.

What is really delightful in this book, and what makes it a monument of industry, care, and patience, is the way in which the life-history, transformations, and habits are worked out; in many cases at a cost of numerous journeys undertaken for this special purpose to remote and difficult parts of the country.

To show the style of the book, we may take the article on "*Œneis.*" First we have four pages devoted to the genus *Œneis*, of which two and a half are descriptive of the imago, egg, larva, and chrysalis; but no allusion is made to the species on which this generic description is based, and nothing, unfortunately, is said as to the allied (some of them very nearly allied) species found elsewhere. This is a grave defect, as, however confident Mr. Scudder may be that *Œ. semidea* is peculiar to the United States, it has at least several congeners of fully equal interest in the Arctic region, a sketch of whose distribution could not be out of place, or without interest to his readers, and would certainly be of more value in almost all cases than very wordy non-comparative descriptions, which nine readers out of ten will entirely overlook. Then we have an excursus, of which there are many interspersed through the work, of eight

pages, giving a charming and life-like account of the White Mountains of New Hampshire and the butterflies found there. This seems to be one of Mr. Scudder's most happy hunting-grounds, and is the only known home, with the exception of the Alps of Colorado, of *Œ. semidea*, the White Mountain butterfly, whose history comes next, and takes up no less than sixteen pages. These include the synonymy and references, which are full and appear accurate; two snatches of poetry (which, by the way, is freely scattered throughout the work); a description of the imago, covering two whole pages of close print; others of the egg, larva, and chrysalis, which take two more; geographical distribution occupies another page. The remainder is devoted to life-history and habits, and ends with a paragraph mentioning the desiderata left to be filled up before our knowledge of the history of the insect is complete.

Not so satisfactory, in my opinion, is the history of *Cercyonis* (*Satyrus*) *alope* and its near congener *nephele*, because, in the first place, not a word is said, in a generic, description extending over three pages, to show how this genus differs (if it does differ) from the genus *Satyrus* or *Hipparchia*, in which the American species are included by other authorities; and, secondly, nothing is said as to whether this generic description is based on the two forms which alone are found in New England, or on the characters of other North American species; which, indeed, are not even named, though their existence is alluded to. As an instance of the difficulty of getting any agreement as to what constitutes a species among butterflies, even when they have been bred as largely, and studied as closely, as this species has been by W. H. Edwards, I may quote Mr. Scudder's remarks:—

"It has been generally conceded of late years that these two types of butterflies were only dimorphic forms of a single species; and I have myself shared in this view, which has been supposed proven by breeding experiments and direct comparisons of a large amount of material made by Edwards, who, far more than all other observers together, has increased our knowledge of the natural history of these butterflies.

"He has instituted comparisons between them at every stage of life; and while he sees differences between caterpillars and chrysalids born of different types, he finds no constant and universal distinctions; while as to the relation of the early stages of the butterflies, he has proved by breeding that 'south of the belt of dimorphism,' as he calls that strip of country where *C. alope* and *C. nephele* both occur, '*alope* produced *alope*,' but inside the belt, *alope* produced intergrades, and *nephele* produced *alope* and also an intergrade. . . . That *nephele*, north of the belt, breeds true, is certain, because the intergrades and *alope* are not found here.

"This would be conclusive if the complete parentage in each case were known; but, as only the mother was known in any case, another explanation is not only possible, but in view of all the facts probable. The intergrades found throughout the belt forming the northern boundary of the typical *alope*, and the southern boundary of the typical *nephele*, seem to be far more easily explainable on the hypothesis of hybridism, since they occur only where such a phenomenon is possible, and wherever it is possible. The same argument applied to the case of *Basilarchia*, as has been done by Edwards, would logically prove more than he would agree to, viz. the specific identity and trimorphism of all the eastern species except *Basilarchia archippus*. That the species of *Cercyonis* here described are certainly distinct, I would by no means maintain; only that, in view of the facts of distribution, it seems more probable that they should be looked upon as having reached in their development the stage of specific distinction, whilst they are readily fertile *inter se*, and produce intergrades, where they meet on common ground."

It seems to me, however, that there is yet another explanation, which, from what we know of the effect of heat and damp on the variation of butterflies of the same family in India, is even more probable; and that is, that the species is one which, having a wide range of distribution, is affected in the southern part of this range by climatic conditions which do not exist in its northern habitat, and has become modified in consequence, whilst in the central part of its range, the climatic conditions being more variable, the insect is also itself more variable. The most ardent devotee of minute subdivision of species cannot fail to allow, after Mr. de Nicéville's experiments on breeding in Calcutta, that climate can and does produce in the same locality, at different seasons, changes which are far greater than the difference which exists between *alope* and *nephele*, a difference which can be matched in other species of Satyridæ, about the specific identity of which there has hitherto been little or no question.

It does not seem to me logical for Mr. Scudder to treat of these two forms as different species, when he allows the specific identity of such forms as *Cyaniris* (*Lycæna*) *pseudargiolus*, *lucia*, *violacea*, and *neglecta*; this view being based, as it must be, on similar breeding experiments, carried out by the same naturalist, who proved to his own satisfaction and to mine the identity of *alope* and *nephele*.

A marked and novel feature of this work, which I cannot too highly praise, is the separated map of geographical distribution given on Plate 18 for most of the species dealt with in this part. On a small chart of the United States and Canada, the range of each species is coloured in brown, so that one can see at a glance what the distribution is; and though, no doubt, in the less known parts of the country these maps are not strictly exact, yet they give a very fair idea of what would otherwise require much reading to understand.

I look forward with the greatest interest to the succeeding parts, and to the early completion of, this most valuable work, which will take a high place among biological monographs, and will rank like Edwards's "Butterflies of North America," as one of the most important, beautiful, and painstaking books which America has ever produced

H. J. ELWES.

POLE'S LIFE OF SIEMENS.

The Life of Sir William Siemens, F.R.S. D.C.L., LL.D. By William Pole, F.R.S. (London: John Murray, 1888.)

IS it perhaps to the spirit of this book-making age that we ought to attribute the fact that examples of unsatisfactory biographies have been frequent in recent years? Perhaps works of this kind are too hurriedly compiled, and are laid before the friends and the public at a date too early to allow of such a memorial proving really satisfactory to the one class or to the other.

The compilation of a biography is almost proverbially difficult. To give a true and unbiased account of a life that has passed away, to show *the man* as he was and as he ought to be known, requires at all times delicacy, and tact, and peculiar ability in the writer to enter into the spirit of the life. The biography of a scientific man and of a great public character requires special gifts besides. But when the friend, the public man, has but recently stood among us, the difficulty is greatly enhanced. To hold the middle course between disclosing too much and too little; to avoid entering into particulars which might prove offensive to friends, or injurious to the material interests of those who are left to carry on the work of him who is gone, and yet to make the biography something more than a mere lifeless catalogue of events and undertakings, of successes and failures—to do this is difficult under any circumstances, almost impossible except after the lapse of many years.

We cannot feel that Mr. Pole's efforts have been crowned with entire success. Undoubtedly he has not erred on the side of indelicately disclosing what should not be made public. But above all things Siemens was sociable and friendly, domestic and hospitable, and ready to throw himself into the concerns of others, whether personal or scientific. This man, always kindly, always lovable, we find too little of in the biography now before us.

We cannot think that the form of writing which Mr. Pole has adopted is happy or advantageous. Chapter III., which gives an account of Siemens's school and college days, will probably be found, by general readers the most interesting part of the book. This is simply on account of the continuity in its style. The remaining chapters are divided into short sections, each with a separate heading in capitals or italics—like an American newspaper. Each one of these little sections gives an account of the progress of some invention during two or three years perhaps. The story then breaks off, and another invention is put before the reader. At the end of the chapter comes a short paragraph headed *Domestic Life*. Then the round recommences. Two or three hundred pages of these paragraphs leave the mind in a state of perfect bewilderment. We admit the difficulty of giving a continuous and interesting account of the life of this many-sided man; but we do not think it has been lessened by this method of treatment.

The letters also which are printed, with the exception of those from Dr. Werner von Siemens, the Berlin brother, are very disappointing. The remainder—from the Shah and other Princes, and from Ambassadors and secretaries of great men—are absolutely without interest. The same must be said of the pages of little obituary notices, many of them three lines long, from the morning and weekly newspapers.

Turning to the subject of the biography, our task is more congenial. A very chequered life lies before us, so far as anxiety and happiness are concerned—great failures, great successes, difficulties which to most men would have proved insuperable, enthusiastic determination and indomitable courage in this man which overcame them all, a life-long struggle steadily growing to remarkable success.

To those who knew Sir William Siemens only as the successful engineer of Palace Houses or the hospitable owner of Sherwood, as President of the British Association or of the Society of Telegraph-Engineers, it is instructive and interesting to trace his early days of mixed failure and success. His ingenuity and inventive power were very striking. At the age of twenty we find him making inventions in connection with electro-plating, governing of steam-engines, printing, &c., patenting them and selling the patents in England. His knowledge at this early age was, naturally, not equal to his enthusiasm and to his inventive fertility. The results obtained were by no means always satisfactory. Sometimes he made a little money: as often what he made by one invention was swallowed up almost to the last penny in endeavouring to realize or to bring forward something new.

Siemens's first undoubted success was his water-meter, in 1852. He had already been engaged in several important undertakings, besides having, early in life, taken many patents, to which we have just alluded; and he had invented and realized his regenerative heating, which subsequently became of the highest importance. But the water-meter supplied a real need in a thoroughly satisfactory way; and it was immediately taken up and yielded him a handsome income. With its success commenced the thorough success of its inventor, and he was thus, as Sir William Thomson remarks, "enabled eventually to find his home among us, and to give us primarily the benefit of his great inventiveness in all directions." It is interesting to chronicle this result, for there are many, to whom the name of Siemens is almost a household word, who have never so much as heard of the invention.

The two great engineering labours with which Siemens's name will always remain associated are electric telegraphy and regenerative heating. With regard to the former, the initiative seems to have come from Berlin, where his elder brother, Dr. Werner von Siemens, had commenced an electrical business about 1844. This business at first consisted in designing and making telegraph instruments; but soon the construction of land lines became a part of the work. About 1848, William Siemens was appointed agent in England for the Berlin firm; and his work grew with its growth. The time was, of course, opportune in the extreme. Soon we hear of the Berlin firm undertaking enormous land line contracts; and, naturally, when the time came, the English firm, which had arisen out of the agency of 1848, commenced to take part in the prodigious English work of girdling the earth with submarine cables. The history of these vast undertakings is most interesting; but unfortunately it is marred in the book before us by the misfortune of being scattered over many chapters, mixed up with a host of matters comparatively unimportant.

With regard to regenerative heating, we cannot do much more than remark that its importance is probably not yet fully realized. One great difficulty Siemens had to contend with was the cheapness of fuel! When he attempted to introduce his method among the salt manufacturers, it was scarcely worth their while to make the necessary changes in their evaporating plant so long as fuel could be so easily obtained. In works on the large scale, such as iron-making and glass-making, the improvements introduced by him are already appre-

ciated; and unfortunately the days cannot be very far distant when economy in fuel will become even more necessary than it is now.

Siemens, as is well known, had greatly at heart the subject of smoke abatement. He applied his principles to the construction of domestic fires, which are the main causes of smoke and fog in many of our large towns. His improvements have not yet to any considerable extent been adopted, but it is greatly to be desired that a reform in this direction should speedily be brought about.

To describe his labours in connection with the introduction of the electric light, the electric furnace, electric transmission of power, electric propulsion on railways, would be quite beyond our limits. We can only refer our readers to Mr. Pole's account of these subjects. The necessary explanations are given with admirable clearness, difficult as it is to compress them into moderate limits; and the book, in spite of our strictures at the commencement of this notice, will be found full of instruction and interest.

SOME PALÆOZOIC DIPNOAN FISHES.

Fauna der Gaskohle und der Kalksteine der Permformation Böhmens. Band II. Heft 3, Die Lurchfische, Dipnoi, nebst Bemerkungen über silurische und devonische Lurchfische. Pp. 65–92, Pls. 71–80. Von Anton Fritsch. (Prag: in Commission bei Fr. Řivnáč, 1888.)

ANOTHER part of Dr. Anton Fritsch's well-known work upon the Vertebrate fauna of the Permian rocks of Bohemia has lately appeared, and the description of the fishes is thus commenced. The nature of the subject does not admit of the introduction of so many novelties as characterized some of the previous parts; but the interest and value of the work is fully sustained, and the discussion of the characters of *Ctenodus*—the only known Dipnoan fish of the Bohemian Gas-coal—is supplemented by some remarks upon a few of its Palæozoic allies, with special reference to the supposed evidence of Dipnoans from the Upper Silurian of Bohemia. In addition to the ten beautifully-executed plates, the text is accompanied by numerous woodcuts, and no less than ten of these represent illustrative fossils that are not Bohemian, while six are devoted to important features in the skeletal anatomy of the living *Ceratodus*.

Dr. Fritsch commences by emphasizing the intimate relationship existing between the genera *Ctenodus* and *Ceratodus*; and each portion of the skeleton of the Permian fish, so far as determinable, is then compared in detail with the corresponding element in the existing genus. The fossils, unfortunately, are for the most part fragmentary, almost all the head-bones being scattered, and none of the bones of the trunk and fins being discovered in natural series; but many can be identified with considerable certainty when rigorously compared according to the author's method.

In the skull of *Ctenodus* there are several ossifications in parts that remain permanently cartilaginous in *Ceratodus*, and the dermal roof-bones are much more numerous than in the last-named genus. A bone that was formerly described as the pelvis of a Stegocephalian is now recognized as the squamosal of *Ctenodus*. There is no certain evidence of maxillæ and premaxillæ; and the mandible exhibits possibly another feature of close agreement with *Ceratodus* in the small size and scale-like character of the bone named dentary by Huxley. Dr. Fritsch considers that the latter element is too insignificant to represent the dentary, and may thus be more appropriately termed "dermomental"; but his argument appears to us far from satisfactory.

An interesting point is remarked upon in connection with the dentition of *Ctenodus*. The commonest of the two species recognized at Kounová was originally founded upon the evidence of detached teeth, and named *Ceratodus barrandei*, Fritsch; but it is now identified with the well-known English Coal-Measure species, *C. obliquus*, Hancock and Atthey. The teeth vary so much in size and so little in characters that Dr. Fritsch represents a series to illustrate several stages in the life-history of the fish; and the small teeth named *C. elegans*, Hancock and Atthey, thus appear to pertain merely to young individuals of *C. obliquus*.

Proceeding to a discussion of the axial skeleton of the trunk, Dr. Fritsch finds evidence of the persistence of the notochord, with the same arrangement of the neural and hæmal arches as is met with in *Ceratodus*. In regard to the parts of the appendicular skeleton, however, satisfactory comparisons are as yet impossible; though it is considered likely that, in the pectoral arch, *Ctenodus* exhibited a greater number of distinct elements than the existing genus.

The scales of *Ctenodus* are large, thin, and round, and the outer surface of each "appears smooth in the middle, and is only seen to be rugose when highly magnified. The border exhibits concentric lines of growth, of varying width, parallel to the margin. Across these extend small parallel ridges, on the middle of which are rows of minute pits, apparently indicating the spots that originally supported denticles." Another noteworthy feature is the forked appearance of the sensory canal upon a detached scale of the lateral line—a condition unknown in *Ceratodus*.

As the result of his researches, Dr. Fritsch concludes that the Bohemian examples of *Ctenodus obliquus* must have attained a length of about 140 centimetres. In every part of the skeleton there is evidence of more complete ossification than is observable in the existing *Ceratodus*; and the occurrence of a greater number of dermal roof-bones in the skull of *Ctenodus* as compared with that of the living Dipnoan is a parallel case to that of the Amphibia previously discussed,—the Permian groups having the skull better armoured than their allies at present existing.

After defining the teeth of a new species (*C. applanatus*) from the Gas-coal of Kounová, and having also briefly noticed another form (*C. trachylepis*) known only by three scales from Nyřan, Dr. Fritsch proceeds, in conclusion, to treat of some of the remains of Dipnoan fishes met with in the Devonian and Silurian, mostly of the Continent. A new genus and species, *Dipnoites perneri*, is indicated by a supposed head-bone from the Upper Silurian of the neighbourhood of Prague. A new and more satisfactory figure of the type-specimen of *Gompholepis panderi*, Barrande, is next given; and this, too, is regarded as

a dermal bone of the cranial roof of a Dipnoan, an interesting bone of *Ctenodus* being figured for comparison. The Old Red Sandstone fossil, named *Phyllolepis concentricus* by Agassiz, is also interpreted as probably the head-bone of a closely-allied fish; and the remarkable skull-fragment known as *Archæonectes pertusus*, H. von Meyer, is considered to be the bony portion of the palate, wanting the teeth.

To the appended synopsis of the literature of the subject, we might add two important papers on *Ctenodus*, by W. J. Barkas, published in the Proceedings of the Royal Society of New South Wales, 1876–77; and the list of known Palæozoic Dipnoan fishes must be reduced by one (*Strigilina*), which is founded upon a tooth of a Selachian. We would also remark that the so-called *Campylopleuron* is almost certainly founded upon the tail of *Ctenodus*, as pointed out by Dr. Traquair (NATURE, vol. xviii. p. 483). In every respect, however, the memoir affords evidence of the most elaborate and painstaking research; and it must long remain a standard work of reference for all who are interested in the palæontology of the Dipnoan fishes.

A. S. W.

OUR BOOK SHELF.

A Revision of the Heterocyst Nostocaceæ. By Ed. Bornet and Ch. Flahault. (Separate reprint with index.) (Paris, 1886–88.)

IN this very important contribution to our knowledge of this interesting group of Algæ, the publication of which commenced in the third volume of the *Annales des Sciences Naturelles*, vii. série (1886), and was concluded in the seventh volume, published this year (1888), we have a work of great labour and research, upon the happy completion of which the authors are to be congratulated.

Those who have investigated the forms of these Algæ will remember the extreme difficulties they have experienced in determining the so-called species of many of the authors whose works they were obliged to consult. Too often it has happened that, unable to recognize a form collected, it has been described as new, and so but added to the big pile of synonyms.

Accepting the division of the hormogonous Nostocs into the two subdivisions of those with "uniform cells" and those with "dissimilar cells," it is with the latter group that the present "Revision" has to do. For many years the authors have investigated all the examples, living or dried, that they could procure. The herbaria of Brébisson, Chauvin, Grunow, Lenormand, Thuret, and the collections of the Museum of Paris, have all been consulted, with the result that an immense mass of described species have been treated as synonyms; while a certain number, of which type-specimens were not to be had, or on account of difficulties of referring them to known genera, have been enumerated as "species inquirendæ."

Introductory to the description of the genera and species we have an account, up to the present state of our knowledge, of the vegetative cells, the filaments, and the trichomes, the outer envelope (cytioderm), the heterocysts, the ramification, the hormogonia, and the spores. Of these two latter modes of reproduction, that by the "hormogones" has been the longest known, and is the one to be found in most of the genera; while that by "spores," destined to preserve the species during the intervals of vegetation, and enabling it to resist desiccation, is known only to occur in some few of the genera, but the authors add "that it is permissible to think that it will soon be known to occur in all." These spores are easily distinguished by their size, their more rounded form, and their more marked granular contents. They often possess a brownish-yellow epispore; in some instances they have been proved to retain their vitality for a considerable time; the spores of *Cylindrosperum licheniforme*, Kutzing, have germinated after a nine years' sojourn in a dried state, in an herbarium. About their behaviour just at the period of germination we have still something to learn. The "conidia" of Borzi are also alluded to. A conspectus of the genera of each of the four tribes of the sub-family is given; the four tribes recognized being the Rivulariaceæ, Sirosiphoniaceæ, Scytonemaceæ, and Nostocaceæ. After the list of genera comes the list of species, with analytical keys and detailed diagnosis of each. There is a very full account of the geographical distribution of all the species.

In a notice the main object of which is to call the attention of our readers interested in these for the most part fresh-water Algæ, it would not be proper to enter into minute details, so we will content ourselves with a statement of our belief that this memoir of Dr. E. Bornet and M. Flahault will not only do very much to assist the botanist, but will also go far to awaken a new interest in a group of plants in which there is abundant field for further research.

E. P. W.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Mr. Spottiswoode's Mathematical Papers.

AT the request of Mrs. Spottiswoode, I have undertaken to edit these papers. Mrs. Spottiswoode has kindly looked over her collection, and put into my hands author's copies of such papers as she has. I still lack the following, which some one or more of the late President's friends may perhaps be able to lend me. The numbers are those of the Royal Society's Catalogue.

I. *Phil. Mag.*, xxxvi. (1850); VI. *Crelle*, xlii. pp. 169–78; VIII. Tortolini, *Annali*, iii. (1852); IX., X. *Camb. and Dub. M. Journ.*, viii. (1853); XIII. R.S. Proc., vii. (1854); XX., XXI. same, xi. (1860); XXII. [as regards Geog. Soc. Proc., v. (1861)]; XXIV. Brit. Assoc. Report (1861); XXV. *Crelle*, lix. (1861); XXXIII. [as regards *Quart. Journ.*, vi. 1864]; XXXVII., XXXVIII., *Quart. Journ.*, vii. (1866); XLVIII., XLIX., and some other papers in the *Comptes rendus* (1874–76). I am especially anxious to receive the *first* part of the "Meditationes Analyticæ," of which we have not found a complete set. *All* the papers are in Mrs. Spottiswoode's library, she believes; but I am anxious to preserve these if possible from passing into the printers' hands.

R. TUCKER.

Statistics of the British Association.

IT is to be feared that the "ladies' curve" in the diagram (NATURE, December 13, p. 153) fails to give anything like accurate information respecting the number of ladies at the meetings of the British Association. Omitting foreigners, the attendance is made up of "members," "associates," and "ladies," but, as a matter of fact, a large number of ladies are members or associates, while only the remainder take "ladies' tickets,"—that is, tickets transferable to ladies, the only transferable tickets issued by the Association.

The column headed "Ladies," in the table (see the Association's Report for 1887, pp. lv.-lvi.) states that 493 ladies attended the last Manchester meeting; but that merely shows that 493 of the ladies who were present took "ladies' tickets," and does not include the lady members and lady associates who were at that meeting. During its meetings the Association publishes lists of the members and associates who are present, exclusive of the holders of "ladies' tickets." By going over the Manchester lists it will be found that upwards of 700 ladies who were either members or associates were in attendance; so that,

including the three groups, more than 1200 ladies attended the Manchester meeting, instead of 493 only. Again, of the ladies at the recent Bath meeting, there were 84 members, *plus* 455 associates, *plus* the, to me, unknown number who took "ladies' tickets."

WM. PENGELLY.

Torquay, December 18.

On the Formulæ of the Chlorides of Aluminium and the Allied Metals.

IN recent numbers of NATURE there have appeared several interesting accounts of determinations of the vapour-densities of certain metallic chlorides. According to the views generally held by chemists, the molecules of some of these chlorides should be represented by the general formula M_2Cl_6, but conclusions are drawn from the experiments described (1) that the formula MCl_3 is applicable to all these chlorides; (2) that the chlorides of the formula M_2Cl_6 are probably incapable of existence in the gaseous state, and that this formula should therefore be given up; (3) that the lower chlorides of these metals should be expressed by the general formula MCl_2 instead of M_2Cl_4, chlorides corresponding to the second formula being incapable of existence.

In view of the great interest that is felt in this question at the present time, it seemed to me that a tabulated statement of the results obtained by various chemists would be of value, in order that a comprehensive view of the question might be obtained:—

It has been pointed out by Messrs. Friedel and Crafts that the method of Dumas has this advantage over that ot Victor Meyer, that the pressure of the vapour can be accurately ascertained, whereas in Meyer's apparatus diffusion takes place to an unknown extent, so that the actual pressure of the vapour is indeterminable.

It appears to me that the following conclusions, which are in general accordance with the views of Friedel and Crafts, may be drawn from the results so far obtained :—

Aluminium Compounds.—The evidence in favour of the existence of the molecules Al_2R_6 is overwhelming, but it is probable that at high temperatures they undergo dissociation, thus $Al_2R_6 = 2AlR_3$,

Gallium Trichloride.—The results point to the existence of Ga_2Cl_6 at low temperatures, and $GaCl_3$ at high, the more complex molecules undergoing dissociation.

Gallium Dichloride.—Most probably $GaCl_2$.

Indium Chlorides.—Formulæ probably $InCl_3$, $InCl_2$, $InCl$; very little indication of the existence of the more complex molecules, but the results are all by V. Meyer's method.

Chromium Chlorides.—The trichloride $CrCl_3$ undoubtedly exists; little or no evidence in favour of Cr_2Cl_6. The dichloride, even at the highest temperature reached, appears to consist largely of molecules of the formula Cr_2Cl_4.

Iron Chlorides.—All the results by Dumas's method, and those of V. Meyer by his own, point to the stability of the molecule Fe_2Cl_6 up to 500° or 600°. The values obtained by Grünewald and Mayer probably point to dissociation into the simpler molecules $FeCl_3$, but since they observed the liberation of free chlorine above 518°, and as the results above 750° are lower even than that calculated for the simple molecule $FeCl_3$, there is clearly necessity for caution in drawing deductions from the experiments.

The values obtained for ferrous chloride indicate, as far as they go, a gradual dissociation of Fe_2Cl_4 into $FeCl_2$.

SYDNEY YOUNG.

University College, Bristol, November 6.

THE UTILITY OF SPECIFIC CHARACTERS.

THE question of the utility or inutility of specific characters is one which is of considerable importance in the philosophy of biology on account of its connection with the action of natural selection ; and it is one which is of special interest at the present time, because of the attention which has been drawn to it by Dr. Romanes's essay on physiological selection, by the Presidential address to the Biological Section at the recent meeting of the British Association, and by various letters and articles in NATURE and elsewhere. This is a matter upon which a biologist who is practically acquainted with species can alone express an authoritative opinion. It is only the naturalist who has an intimate knowledge of the characteristics and the habits of species who can judge accurately of the relations between such structural features and the animal's habits and surroundings, and who can appreciate the fact that many structures or variations of structure may be of importance, although their precise functions and relations to environment may not yet be known.

The more minutely a group of organisms is studied, the more the object or utilitarian significance of the specific characters becomes evident. In the Tunicata, the class of animals I happen to have paid most attention to of late years, I am convinced of the practical importance or usefulness of the recognized specific modifications :—such as the condition of the muscular system, the arrangement of the vessels in the branchial sac, the number and arrangement of the tentacles, and so on—these structures being all related to most important functions, such as respiration and the regulation of the food-supply. Even in the case of such apparently trivial characters as the shapes and

distribution of the minute spicules throughout the colonies of *Leptoclinum* and some other Compound Ascidians, I know from experience that they affect the hardness and roughness, as well as the colour, of the colony, and so may be of considerable importance in repelling enemies and in keeping the colony free from injurious parasites. As a matter of observation, I find that the colonies of Didemnidæ (which are provided with calcareous spicules) are much freer from both external and internal parasites than are the softer-tested Compound Ascidians.

During the last few years I have had occasion to study closely the fauna of the sea-shore at different parts of our coast. I have spent many hours on the rocks at Puffin Island and elsewhere at extreme low water, watching the animals in the pools and under the ledges in their natural conditions. Such work impresses very forcibly upon the observer the reality and importance of such fundamentals of evolution as variation, over-crowding, and struggle for existence, the action of natural selection, the benefit of protective colouring, the completeness and the advantage of mimicry, the benefit of spicules, shells, various shapes, &c., the purposes and origins of peculiar habits, the complicated relations between the animals and their environment, and finally the utility of specific characteristics.

Of all the regions of sea and land, so far as my limited experience goes, by far the most prolific of animal life is that region of the shore which is known as the upper edge of the Laminarian zone. It lies just beyond the ordinary beach, and is only exposed at the lowest spring tides. There, amongst the tangled masses of *Laminaria*, especially if there are large irregular stones with many pools and crevices between, marine invertebrate life is to be seen in very great profusion ; in a favourable locality, such as Puffin Island, all the chief groups of marine animals being abundantly represented. There, competition is probably very keen amongst allied forms of animals, and the conditions necessary for natural selection to take place, and the results of that process, may most advantageously be studied.

I have lately been noting which animals in this region of the shore appeared to be the most conspicuous by their colour or shape or other peculiarities on various occasions and in different localities, with the object of seeing how far the want of protective colouring or attempt at concealment can be accounted for ; and the result is that, so far as I have observed, all the most brightly-coloured or otherwise very noticeable species are provided with some defensive or offensive contrivance which appears to protect them from enemies. Amongst these conspicuous forms are: the white calcareous and some of the scarlet and other brightly-coloured siliceous Sponges (which are well protected by their numerous pointed spicules), the gleaming white Compound Ascidians (provided with sharp-pointed calcareous spicules), some of the Annelids (protected by their setæ, elytra, &c.), some of the Polyzoa, such as the Escharidæ and other incrusting forms (covered by calcareous ectocysts, often provided with spines and other projections), and a few erect forms such as *Bugula* (which are protected by the presence of numerous sharp-beaked snapping avicularia). The bright orange-coloured *Bugula turbinata* is certainly one of the most conspicuous animals on certain parts of the shore about low-water mark at Puffin Island. Of course such protective characters as these animals possess are not all necessarily specific, but may be generic, or characteristic of still larger groups, and I am not now citing them as instances of useful specific characters, although I do not doubt they would prove such, if the details were properly worked out.

As examples of these last (useful specific characters), I would point to the distinctive features of the species of Ascidians, where even the very varied external shapes may be regarded as useful modifications, since they allow of, or correspond to, particular forms of the muscular mantle and the branchial sac and the other viscera within the test, and of course the shapes of the mantle and branchial sac are of functional importance. It is important to note that the one external feature which it is difficult to see any use in—viz. the number of lobes surrounding the branchial and atrial apertures—is *not* a specific character, but is distinctive of genera, and even more so of families and sub-families.

On passing to the interior of the body in the Ascidians, we find that the best-marked characters are taken from the condition of the mantle and of the branchial sac, and its neighbouring structures the tentacles and the dorsal lamina. Now, these are all organs with most important functions to perform in regard to respiration, nutrition, the circulation of water through the body, and the collection and agglutination of food-particles. And all the structural modifications found are such as must evidently be of actual use to the possessors. The current of water passing through the body of an Ascidian—in at the branchial aperture, through the stigmata in the walls of the branchial sac into the atrial cavity, and from that out by the atrial aperture—is of primary importance, since it serves the following purposes : (1) it conveys oxygen into the body for respiratory purposes, (2) it brings the food-matters into the body, (3) it removes waste matters from the body, and (4) it conveys to the exterior the ova and spermatozoa. This current of water is caused and guided by (*a*) the shape of the mantle and the arrangement of the sphincters and other muscles, and (*b*) the cilia covering certain of the vessels and other parts of the wall of the branchial sac. Hence modifications of the form of the mantle and of its muscles, and of the vessels, bars, papillæ, &c., forming the wall of the branchial sac (which are precisely the characters made use of in distinguishing the species), must surely be of functional importance, or, in other words, are useful modifications, such as would be produced by the action of natural selection.

It is scarcely necessary to call attention to such important adaptive characters as the arrangement of the blood-vessels and water-passages in the walls of the branchial sac, but it may be pointed out that even such trivial structures as the spine-like scales lining the branchial siphon in some Cynthiidæ may well be more or less useful, according to their shape and size, in keeping out small unwelcome intruders, such as the young of the parasitic Copepoda, sometimes found in the branchial sacs of some Ascidians.

Another point in which species of Ascidians differ is the condition of the tentacles round the entrance to the branchial sac—*i.e.* their number, shape, branches, and arrangement. These organs probably perform various functions: they break up and distribute the currents of water, they intercept and guide the food-particles, they probably act as sensory organs, and they form a more or less perfect grid for preventing large objects from entering the branchial sac. Hence there can be little or no doubt that in this case also the various modifications are really useful.[1]

These few instances are, perhaps, sufficient to show that, in the Tunicata at least, specific characters are of actual importance to their possessors, and are adaptive modifications such as would be produced by the action of natural selection ; and I fancy that the same will be found to be the case in other groups of animals, if those biologists who are intimately acquainted not only with the characters of the various species, but also with their habits in a condition of nature, and the environment generally, would turn their attention to the matter.

W. A. HERDMAN.

[1] I am working up the matter in further detail for the Report upon the Tunicata in the second volume of the "Fauna of Liverpool Bay."

THE INTERNATIONAL BUREAU OF WEIGHTS AND MEASURES.

ALTHOUGH the International Bureau of Weights and Measures has now been in existence for some years, its work hardly appears to have been so generally recognized as it ought to be. This may be owing partly to the fact that the results of its labours are published in volumes accessible only to a few; and, partly, that the researches of the Bureau, being in the direction of the highest accuracy in physical measurement, are hardly appreciated at first in the every-day work of ordinary life. It may be well, therefore, to mention briefly the contents of the five annual volumes of the Bureau which have already been issued, before noticing the contents of the sixth volume which lately reached us.[1]

The first volume issued in 1881, under the immediate direction of Dr. O. J. Broch, gives the results of the researches made at the Bureau on the tension of aqueous vapour; on the fixed points of thermometers; on the true weight of a litre of air; and on the specific gravity of water. The second, third, and fourth volumes contain papers on the dilatation of the standard metres; on the weighing of the standard kilogrammes; and on the dilatation of mercury. In the fifth volume may be found an exhaustive consideration of the methods of verifying subdivided linear measures; of calibrating thermometers; and of correcting the progressive errors of micrometer screws. This latter volume also contains thermometric studies; as well as studies of the theory of the balance as applied to scientific weighings.

The new volume (tome vi. pp. 620) contains three papers, one by Dr. René Benoît, on the measurement of dilatations by the method of M. Fizeau; one on the comparison of mercurial thermometers with the air or hydrogen thermometer, by Dr. P. Chappuis; and a third paper on practical formulæ for the transformation of thermometric coefficients, by Dr. A. E. Guillaume.

M. Fizeau's method of determining the rate of expansion of solid bodies by heat is well known (*Annales de Chimie et de Physique*, 1864-66), but its application has hitherto been difficult. Dr. Benoît has succeeded in removing this difficulty, and by clear explanation and complete formulæ of reduction, has brought the use of this dilatometer within the reach of the ordinary student. We regret that our space prevents us giving an outline of Dr. Benoît's methods and a sketch of the particular form of dilatometer he uses; the following, however, are the coefficients of linear expansion for 1° C., from 0° to t°, as ascertained by him during the past year:—

Quartz—Direction parallel to the axis	$\alpha = +0{\cdot}0000071107$; $\beta = +0{\cdot}00000000856$
Direction perpendicular to axis	$\alpha = +0{\cdot}0000131620$; $\beta = +0{\cdot}00000001263$
Beryl—Direction parallel to the axis ...	$\alpha = -0{\cdot}0000013403$; $\beta = +0{\cdot}00000000403$
Direction perpendicular to axis	$\alpha = +0{\cdot}000009942$; $\beta = +0{\cdot}00000000465$
Platinum	$\alpha = +0{\cdot}0000088405$; $\beta = +0{\cdot}0000000189$
Platinum-iridium (Mr. Matthey's alloy, Type I.)	$\alpha = +0{\cdot}000008615$; $\beta = +0{\cdot}00000000221$
Gold coin, English sovereign and half-sovereign	$\alpha = +0{\cdot}000014472$; $\beta = +0{\cdot}00000000421$
Steel cast by Messrs. Jessop and Sons ...	$\alpha = +0{\cdot}000010387$; $\beta = +0{\cdot}00000000595$
Brass and Bronze— Copper, 73·75; Zinc, 24·18; Lead, 0·57; Tin, 1·52	$\alpha = +0{\cdot}000017820$; $\beta = +0{\cdot}00000000584$
Copper, 81·20; Zinc, 8·60; Lead, 0·17; Tin, 9·87	$\alpha = +0{\cdot}000017431$; $\beta = +0{\cdot}00000000618$
Phosphor Bronze (rich in phosphorus, hard)— Copper, 94·6; Tin, 4·7; Phosphor, 0·7	$\alpha = +0{\cdot}000016881$; $\beta = +0{\cdot}00000000618$

Dr. Chappuis states that since the study of the mercurial thermometer has shown that this instrument is susceptible of the greatest precision, there has been recognized a necessity for stating its indications in a scale unique and invariable. The choice of such a scale presents serious difficulties, for even in the best measurer of temperature—as Regnault's air or gas-thermometer—practical measurement is dependent on the limits of pressure between which the measurement is made, and on the nature of the air or gas used. The mechanical theory of heat has given a new definition to temperature, independent of any supposition as to the regularity of the dilatation of bodies, and furnishes therefore an absolute scale of temperature, which, on the supposition that a perfect gas is used, should accord with the definition of temperature of the gas-thermometer.

A rigorous verification and intercomparison have therefore been made by Dr. Chappuis of a gas-thermometer of large capacity, with eight of Tonnelot's hard-glass standard mercurial thermometers. He found that the scale-readings of the mercurial thermometers differ as follows from the scale-readings of air, hydrogen, and carbonic-acid thermometers, the hydrogen-thermometer presenting the greatest divergence:—

0°·107 C. at 40° C. for hydrogen,
0°·097 ,, 40° ,, air,
0°·049 ,, 35° ,, carbonic acid;

the difference in the march of the air and hydrogen thermometers (7), and between the carbonic acid and hydrogen thermometers (8), being represented by the following formulæ:—

$$(7)\quad T_{Az} - T_H = +0{\cdot}00542995(100 - T_m)T_m + 1{\cdot}4118126 \times 10^{-4}(100^2 - T_m^2)T_m - 1{\cdot}322986 \times 10^{-6}(100^3 - T_m^3)T_m.$$

$$(8)\quad T_{CO^2} - T_H = +0{\cdot}03591397(100 - T_m)T_m - 0{\cdot}2340806 \times 10^{-4}(100^2 - T_m^2)T_m - 0{\cdot}510047 \times 10^{-6}(100^3 - T_m^3)T_m.$$

Dr. Benoît has accordingly given the coefficients of expansion of the several bodies above referred to in terms of mercurial thermometers made of crystal glass and of hard glass respectively, and of the hydrogen thermometer; of which the following is an instance:—

Linear Coefficients of Dilatation for 1° *C.*

By mercurial thermometer made of crystal glass.	By mercurial thermometer made of hard glass.	By the hydrogen thermometer.
GOLD (English Standard, 1½)		
$10^{-9}(14473 + 4{\cdot}27t)$ ...	$10^{-9}(14497 + 4{\cdot}03t)$ ...	$10^{-9}(14571 + 3{\cdot}19t)$
PLATINUM.		
$10^{-9}(8840{\cdot}5 + 1{\cdot}89t)$ ...	$10^{-9}(8855 + 1{\cdot}74t)$ ...	$10^{-9}(8901 + 1{\cdot}21t)$

We have recently called attention to the fact that the work of the Comité International des Poids et Mesures is now approaching completion, so far as relates to the delivery to each country of a verified copy of the metric standards of measure and weight, the prototypes of which are to be kept and maintained at the offices of the Bureau, situated at the Pavillon de Breteuil, Sèvres, near Paris; and we are glad to see from the *Procès-verbaux*, also recently issued by the Comité, that the Government of this country have requested the Comité to furnish the Standards Department of the Board of Trade with exact standards of the metre, and of the kilogramme, made in platinum-iridium.

[1] "Travaux et Mémoires du Bureau International des Poids et Mesures," tome vi. (Paris: Gauthier-Villars et Fils, 1888.)

ON THE PLASTICITY OF GLACIER AND OTHER ICE.[1]

THE nature of the motion of glaciers has been the subject of an immense number of observations by Forbes, Agassiz, Schlagintweit, Tyndall, &c., and the following facts amongst others have been established.[2] (1) The velocity decreases gradually and continuously from the centre to the sides, where it is sometimes almost imperceptible, though in other cases it reaches one-third of its value at the centre. (2) The motion is in general continuous from day to day, and even from hour to hour. (3) The motion is generally most rapid at the hottest time of the year, and slowest at the coldest, the ratio being often 4 to 1. But the effect of temperature is at present by no means properly worked out.

One main result of these observations may be summed up in the statement that a glacier moves like a plastic body. The most natural conclusion would be that ice is plastic. But this conclusion was for a long time almost universally rejected. Hand specimens of ice show no sign of plasticity to casual observation, and no doubt few people realized what very slow yielding under stress would account for the observed motion. So the rigidity of ice was treated as an obvious fact. At any rate I have not come across any mention of careful experiments which failed to show plasticity within a few degrees of the melting-point. As will be seen below, however, such results might readily have been obtained on suitable ice.

True plasticity, then, being rejected, some other explanation had to be found. The one generally adopted is due to James Thomson. He proved theoretically that the freezing-point of water is lowered by pressure at the rate of 0°·0075 C. per atmosphere. This was afterwards verified experimentally by Sir Wm. Thomson. The former held further that any kind of stress lowers the freezing-point. Now glaciers are believed to be throughout at or very near the temperature 0° C. Thus the ice should melt at places where the stress is most severe, and an equal quantity should be formed elsewhere. There are at least two difficulties in this explanation. In the first place, the melting must absorb heat, and the work done by pressure in the contraction of volume is quite an insignificant source of heat. So the temperature would be immediately lowered, and the process be brought to a standstill, before it had well commenced, unless heat were supplied by conduction. When we remember that, even when the stress is most severe, the melting-point is only lowered a few hundredths of a degree, and that there must be considerable distances between points of great stress when the ice melts, and points of little stress when it forms, it is difficult to believe that sufficient heat can be conveyed from one to the other to produce much effect. Some rough experiments I have made show ice to be a far worse conductor than any rock, and nearly as bad as wood. In the second place, it has yet to be proved that the mass of the glacier is permeated by water. Recent experiments by Prof. Forel (*Arch. des Sciences Phys.*, Geneva, July 1887) go far to show that the capillary fissures containing water are confined to the surface layer.

But the point which I especially desire to bring out is that this explanation is confessedly only a way out of a dilemma. If glacier ice can be shown in the laboratory to be plastic, the dilemma no longer exists, and there is no necessity to have recourse to any other explanation until it can be proved that the plasticity is insufficient, or otherwise fails to account for the observed facts. The existence of this plasticity in glacier ice we claim to have established in our experiments last winter.

The false plasticity due to melting and regelation is put out of the question by operating at a temperature below even $-0°{\cdot}1$ C., for to lower the melting-point by a tenth of a degree requires a pressure of thirteen atmospheres. If true plasticity is found at lower temperatures, it is impossible to deny its existence at the melting-point itself. And plasticity has been found several degrees below 0° C. by many experimenters, such as Matthews, Bianconi, Aitken, Pfaff, &c.[1] Most of their experiments were made on the bending of bars, in which case the stress is too complicated to furnish any but the vaguest idea of the relation between strain and stress. Further, none of them dealt with glacier ice, for I do not include the experiments of Coutts Trotter, made at 0° C.

Matters were in this state when Dr. Main began his experiments at St. Moritz the winter before last (Roy. Soc. Proc., vol. xlii. p. 329). A winter sojourn in the Engadine affords peculiar facilities for experiments of this nature. During December, January, and February, one can count on almost continuous frost. In a room on the north side of the house, with the window kept permanently open, the temperature seldom rises above the freezing-point. Dr. Main wished not merely to settle the question of the existence of plasticity, but also to determine accurately its amount under various conditions of stress and temperature. He decided to apply tension. This has great advantages over other kinds of stress for purposes of accurate measurement, as it is comparatively easy to isolate from other stresses. Pressure, for instance, applied to the ends of a bar of ice makes it bend, and we have then a complicated set of stresses to deal with. And if the bar be so short and thick that bending is improbable, the contraction to be measured becomes very small. There are, however, certain obvious inconveniences in applying tension, viz. the difficulty of getting a good grip of the ends of the bar of ice, and the constant risk of fracture.

Main used a mould for his ice, which turned out a round bar with a conical enlargement at one end, which would fit into a conical iron collar. A conical piece of ice fitting another collar was frozen to the other end of the bar of ice, and the tension was applied through the two collars. Accurate measurements of the distance between the collars were taken from time to time. In this way he established the existence of plasticity in this kind of ice at all temperatures down to $-6°$ C. It is to be noticed that the ice cones are subjected to both pressure and shearing stress, and some of the observed extension must have been due to the distortion of these cones; but that nearly all of it was due to pure tension in the bar he found by measuring the distance between marks on pieces of paper gummed on to the bar itself. In this last way he found the bar extended during three days at the rate of 0·02 mm. per hour per length of 10 cm., while the temperature remained below $-2°$.

As his health prevented him from spending last winter at St. Moritz, he suggested that I should continue the experiments, kindly putting all his apparatus at my disposal. I should not have been able to carry out such an undertaking had I not been fortunate enough to secure the assistance of an able coadjutor in Mr. Kidd, on whom fell by far the greater part of the labour of experiment. We started, like, I believe, all investigators before us, under the impression that one piece of clear ice would do as well as another, no matter how it had been formed. Thus it was merely owing to the difficulty of obtaining clear ice in the mould that we took our first experimental bar from a different source. We imagined that since Main had established the fact of extension under tension, all that was left was to determine its amount at various temperatures and under various tensions. So we were a good deal surprised by the behaviour of our first bar. It practically refused to stretch. We had taken the pre-

[1] For full details of the experiments herein described see a Paper by James C. McConnel and Dudley A. Kidd, published in the Royal Society's Proceedings, June 1888.

[2] See Heim's "Gletscherkunde," published by Engelhorn, Stuttgart, 1885.

[1] See NATURE, vol. xxxii. p. 16. and Heim, *loc. cit.* p. 315, who cites a paper by Matthews, *Phil. Mag.*, 1869.

caution of observing the extension of the bar proper by measuring the distance between two needles fixed in the bar near either end. We used a cathetometer in the first instance, but that generally unsatisfactory instrument was particularly untrustworthy in our circumstances, and the small extension we found may have been due to errors of reading. We applied, therefore, a system of light levers to the needles, which would indicate a very minute extension, though it was not well adapted to measure large extensions with accuracy. Under this far more severe test, the bar still maintained its rigid character. Between two of the readings there was a slight extension of 0·044 mm. This we attributed to a sort of surface crack which we found in the bar after the experiment. With this trifling exception, the whole of the lengthening seemed to be caused by a gradual rise of temperature which took place. This supposition gave, indeed, a coefficient quite concordant with the latest results obtained by others. Even without making any allowance for the rise of temperature, the mean rate of extension during six days was less than 0·0002 mm. per hour per length of 10 cm., about 100 times as small as Main had found. This enormous difference had nothing to do with either the temperature or the tension, for the former averaged about the same and the latter was slightly greater in our experiment. The cause evidently was to be sought in the nature of the ice itself, and we were not long in discovering a satisfactory explanation.

Ice is, as is well known, a crystalline body, and its molecular structure is no doubt perfectly regular and definite so far as it is revealed by the polariscope or spectrometer. We have no reason to expect any bending of the optic axis or gradual change of the indices of refraction within any one crystal. Every piece of ice, therefore, is either itself a single uniform crystal, or is built up of pieces, each of which is a single uniform crystal. Thus, bars of ice fall into two classes—homogeneous and heterogeneous. Main's bars were heterogeneous, ours was homogeneous. We concluded, therefore, that *heterogeneous ice is plastic, while homogeneous ice is rigid;* and this conclusion was confirmed by subsequent experiment.

It is generally impossible to tell with the naked eye whether a piece of ice is heterogeneous or homogeneous. But a polariscope settles the question at once. We put together a rude form of polariscope in which the light from a sheet of white paper is reflected at an angle of 57° by a pile of three glass plates towards a Nicol prism held in the same framework. We generally turned the Nicol so as to make the field dark. Looking through the Nicol, and holding a bar of heterogeneous ice between the Nicol and the glass plates, some of the crystals would look dark, some light, and some, perhaps, coloured. If the crystals overlapped and interlaced much, the appearance was very complicated; but in any case it was easy to make out the line where the interface of any two crystals cut the surface of the bar. Our first bar was square, with the optic axis at right angles to two of the sides. It was about an inch thick, and it showed under the polariscope the coloured rings and black cross of a uniaxial crystal very well. And these remained stationary and unbroken while the bar was moved parallel to itself across the field of view, showing that it was a single crystal. To obtain the ice we had put out a large bath of water in, as it happened, comparatively mild weather, and cut the bar from the ice formed at the top. The water was from the ordinary hotel supply, the same as had been used by Main.

Glacier ice, as is well known, is markedly heterogeneous, being composed of irregular lumps accurately fitting each other, each of which is a single crystal. These lumps are called in German *Gletscherkörner*, and in French *grains du glacier;* so in English we may use the term glacier grains. They are found of all sizes, from that of a pea to that of a melon. But the average size diminishes rapidly as we follow a glacier upwards towards its source. At the surface of a glacier the ice is of course quite disintegrated by the sun, and the original structure has vanished, and on the side of a crevasse or in an ice cave where the clear ice is seen, the grains are frequently quite indistinguishable with the naked eye. But, if a fragment of this clear ice be exposed to the sun for a few minutes, the dividing surfaces of the grains come out very clearly through thin films of water being formed. Moreover, in each crystal a number of small disks appear, perhaps the tenth of an inch in diameter, with their planes at right angles to the optic axes. This peculiarity helps to mark off one grain from another.

On account of this structure it was probable that glacier ice would prove to be plastic; but it would have been extremely rash to repeat the mistake into which others had fallen, and deduce the properties of glacier ice from experiments on other ice. Fortunately, it was an easy matter to obtain access to a glacier. For the restaurant at the foot of the Morteratsch Glacier and the road thereto are now kept open in winter, and the distance from St. Moritz is only eight or nine miles. We procured some pieces from the natural ice caves, whence the stream issues at the foot of the glacier, and sawed them into bars at our leisure. We tested three bars, which put beyond a doubt the plasticity of glacier ice under tension. The rate of extension varied, however, in the most extraordinary manner in each bar, not merely with the temperature and the tension, but also with changes in the nature of the bar, due, apparently, to the process of extension itself. To make the results obtained with different bars comparable, I shall give all the rates of extension in millimetres per hour per length of 10 centimetres. The first bar extended at a rate of from 0·013 mm. to 0·022 mm., the variations being attributable to changes of temperature. The second began at a rate of 0·016 mm., and gradually slowed down till it reached at the same temperature a rate of 0·0029 mm., at which point it remained tolerably constant, except for slight temperature fluctuations, until the tension was increased by one-half. This brought the rate at once up to 0·0110 mm. This increased rate in its turn showed a tendency to sink, more or less counterbalanced by a rising temperature. This piece of ice was under tension for twenty-five days, and extended altogether about 3 per cent. of its length. The third piece behaved in a very different manner. It began at the rate of 0·012 mm., increased its speed, with the tension nearly doubled, to 0·026 mm., and stretched faster and faster, with unaltered tension, till it reached the extraordinary speed of 1·88 mm. We put on a check by reducing the tension by one-third, whereupon the speed fell at once to 0·35 mm., and gradually declined to 0·043 mm. The lowest temperature reached during our experiments, except with the intractable bath ice, was with this specimen. For twelve hours the temperature never rose above $-9°$, and it probably averaged $-10°·5$. The tension happened to be very light—only 1·45 kilos per sq. cm.; but the rate was easily measurable. It was 0·0065 mm. The arrangement of the grains in these bars was too complex for description. The size averaged, perhaps, that of a walnut. Nearly one-third part of the third piece was one crystal, which ran three-quarters of the length between the needles.

Some, though not all, of the ice of the St. Moritz Lake is possessed of a curious structure. It is built up of vertical columns whose sections are of quite irregular shapes. The thickness of each column is not quite uniform; still, the sides are nearly vertical. An average column is about as thick as an ordinary pencil, and in length is only bounded by the depth of the clear ice—*i.e.* a foot or more. Each column is a single crystal, and the optic axes are generally nearly horizontal, though otherwise arranged at random. The columns become visible

to the naked eye when the ice begins to melt, and, if this melting is caused by sunshine, they often become quite detached and fall apart. The appearance presented on the lake when the ice melts in the spring is described as very curious. The crackling of the breaking columns, when the loose ice drifts against the shore, can be heard at some distance. It would be interesting to learn if such columns have been noticed in England. (Prof. Heim informs me that he has found a columnar structure in lake ice in the Swiss lowlands, but the optic axes were all vertical.) A few experiments we made on freezing water in a bath led us to attribute this structure to the first layer of ice having been formed rapidly—for example, in air below $-6°$ C. No doubt the nature of the first crystals formed settles the structure of all the rest of the ice.

This lake ice afforded a capital opportunity for testing our notion that the crystals themselves are rigid, and that the apparent plasticity is due to some action at the interfaces of the different crystals. We first tried a bar whose length was parallel to the columns. This was, really, trying to stretch a bundle of long thin crystals. We were able to measure an extension, but it was excessively small, amounting to about 0·12 mm. on one side of the bar and 0·07 mm. on the other during 208 hours, giving a mean rate per hour per length of 10 cm. of 0·00046 mm. I do not believe that the crystals stretched by even this small amount. For those that were slightly inclined to the direction of pull would be pressed against their neighbours, there would be yielding at the interfaces, and consequent minute lengthening of the bar. We next cut a bar such that the columns ran in a slanting direction across it at an angle of about 45° to the length. The difference was very striking. The new bar stretched at a rate of 0·015 mm. per hour per length of 10 cm.,—more than thirty times as fast.

Towards the end of the winter we determined to try the effect of pressure, and after some thought decided on the following arrangement, which proved in practice very satisfactory. We found in Dr. Main's stock two sheets of thick plate glass, about 25 centimetres by 17. We laid one of these on the table, on it three pieces of ice, and on them the other glass plate. The three pieces were cut as nearly alike as possible, each being about an inch cube. So they were short and thick enough to preclude the likelihood of bending. They were arranged at the angles of an equilateral triangle 9 cm. in the side. Pressure was applied by means of a lever and weight at a point vertically over the centre of this triangle, so the pressure on each block of ice was the same. Measurements of the distance between the plates were taken with calipers at three points at the edge, so selected that it was easy to calculate from the measurements the contraction of each block. Our first experimental result was that the coefficient of friction of ice on glass is very small. The moment the weight was applied, the three pieces of ice shot out on to the floor. Afterwards this inconvenient tendency was held in check by freezing pieces of paper on to the ends of the blocks.

Three pieces of glacier ice showed that this substance is just as amenable to pressure as to tension. The mean rates during five days were respectively 0·035 mm., 0·056 mm., and 0·007 mm. per hour per length of 10 cm. We could not discover any material difference between the three under the polariscope. They were all composed of smallish grains averaging perhaps 7 mm. in diameter, and all three were from the same lump. They were under exactly the same conditions of temperature, and under, at any rate nearly, the same pressure, and yet the second piece gave eight times as much as the third. Of course the arrangement of the interfaces was very complicated in both pieces, and it may have been much less favourable to distortion in the third, but it seems more probable that there was some obscure difference in the state of the interfaces. Bubbles, at any rate, seem to have had no bearing on the matter, for the third piece contained far the most, and the first piece the fewest.

We next tried lake ice with the columns vertical. The mean rate of the three pieces during four days was 0·001 mm. per hour per length of 10 cm. This was only just perceptible to the calipers, and we think it may have been entirely due to the yielding of the films by which the paper was attached or to the same cause as in the case of tension.

Our evidence for the rigidity of an ice crystal rests on three experiments. One of these was on a single crystal of the bath ice, and tension was applied; and the other two on lake ice with the stress applied parallel to the columns: tension in the first case, pressure in the second. These showed that the plasticity of an ice crystal is either non-existent, or is at any rate of a very different order of magnitude from that of ordinary heterogeneous ice. The optic axis in the first case was exactly at right angles to the stress, and in the two latter it was not very far from that position. It would have been perhaps more satisfactory if we had applied stress in other directions. But it seems, *a priori*, very unlikely that any homogeneous substance should be rigid in one direction and plastic in another, and in our Royal Society paper we have given more conclusive reasoning to show that the rigidity must extend to the direction parallel to the axis.

If a bar composed of a number of crystals of irregular shape stretches, while remaining compact, the crystals must necessarily change their shape. It is probable, therefore, that molecules separate themselves from one crystal, and moving across the interface attach themselves to another. But to unravel the laws which govern the direction and rate of the motion of the molecules further experiment is necessary. Mr. Buchanan's experiments, recently described in NATURE (vol. xxxv. p. 608, xxxvi. p. 9), throw some light on the matter. They render it likely that a large part of the soluble impurities in the ice will be collected at the interfaces, and will keep a certain amount of water in the liquid state. This liquid, however, must be a very thin film, for it does not interrupt the optical continuity. If the thickness of the film were not small compared with a mean wave-length of light, there would be reflection, and the interface would be visible to the naked eye. Nevertheless an invisibly thin film might play a very important part in providing a mobile medium for the transmission of the molecules. According to Mr. Buchanan, the amount of liquid present would be roughly inversely proportional to the number of degrees below 0° C. This law is very accurate near 0° C. With any one salt the amount of liquid at low temperatures would be rather greater than is given by the law, but at a certain temperature, the freezing-point of the cryohydrate of that salt, the liquid would completely solidify. According to Guthrie, the cryohydrate of $CaCl_2$ freezes at $-37°$ C., of NaCl at $-22°$, of Na_2SO_4 at as high a point as $-0°·7$. If this thin film of liquid be an essentia factor, ice should be perfectly rigid at a temperature low enough to freeze all the cryohydrates. On the other hand, the amount of liquid should become indefinitely great as zero is approached, so that the plasticity might be expected to be very largely increased when the air surrounding the ice rises above zero. We did not find this was the case. In a tension experiment on an icicle, the surrounding air for five hours was at about $+0°·5$ C., and yet the rate of extension was not strikingly greater than it had been a few degrees lower.

The temperature variations proper were so small compared with the irregular variations spoken of above, that it was difficult to secure any satisfactory measure of them. Still, I have a few figures to offer. In the case of the second piece of glacier ice, while at $-3°·5$ the rate was 0·0029 mm., two days before and two days afterwards it was about 0·0020 at $-5°$, and a few days earlier 0·0013

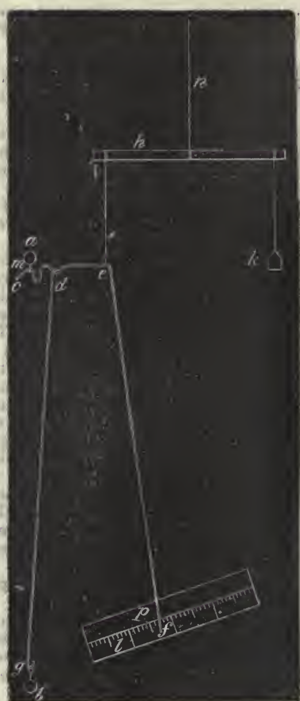
at $-8°$. In the icicle, when the temperature variations seemed paramount, the rate at $-2°$ was 0·0028; and at $-0°·2$, 0·0034. Under pressure the influence of temperature seems much more powerful. In all three pieces of glacier ice the rate rose at $-3°$ to about ten times its value at $-5°$.

The effect of a change of tension was very striking. I append a list of all the cases which occurred.

Specimen.	Change of tension: kilos per sq. cm.	Change of rate: mm. per hour per 10 cm.
Glacier ice C	2·55 to 3·85	0·0018 to 0·0110
Glacier ice D	1·45 ,, 2·55	0·0075 ,, 0·026
,, ...	2·55 ,, 1·03	0·105(?) ,, 0·010
,, ...	1·03 ,, 2·50	0·010 ,, 0·228
,, ...	2·50 ,, 1·80	1·88 ,, 0·35

The 0·105 is uncertain owing to an accident. It was certainly not less, and may have been a good deal greater.

I think it will be interesting to describe the system of levers which we found so effective in measuring small extensions. It is shown in the figure. *a* and *b* are sections of the projecting ends of glass needles fixed in the ice from 12 cm. to 20 cm. apart; *cdef* is a bent iron wire, "the indicator," hooked to a wire loop, *m*, securely fastened to *a*; *h* is a wooden lever suspended by a thread *n*, which, owing to the counterpoise *k*, pulls the indicator upwards with a thread fastened to a wire loop at *e*. The indicator is kept from rising by the connecting fibre, a piece of stiff wire hooked at one end to the loop *g*, fastened to *b*, and at the other to a bend d^1 in the indicator. The lower end of the indicator gives the reading on a paper millimetre scale *l*, gummed on to the mirror *p*. The mirror, of course, enables the observer to avoid errors of parallax. The stand of the mirror is glued to the lower collar. To appreciate the action of the levers, regard *a* for the moment as fixed, then lowering *b* through a small distance *r* will move *f* through a distance $s = vr$ at right angles to *mf*, where *v* is the ratio of the distance *mf* to the perpendicular let fall from *m* on the line *gd* produced if necessary. If *md* be the perpendicular to *gd*, when *f* is in the middle of the scale, the multiplier *v* remains practically constant. This precaution was not always taken, but allowance is made for the resulting error. Two lever systems were required, one for the outer ends, and the other for the inner ends of the needles passing through the ice.



In the following table is given a summary of our results:—

SUMMARY. *Extension Experiments.*

Description of specimen.	Duration.	Rate per hour in mm. per length of 10 cm.	Tension, kilos per sq. cm.	Maximum temperature.	Mean temperature.
Bath ice uncorrected for temperature	5½ days	0·00028	4·9	$-1°·0$	$-4°·5$
,, corrected for temperature	,,	0·00000	,,	,,	,,
Mould ice	28 hours	0·048	3·8	0·0	$-5·0$?
Glacier ice A, maximum rate	5 ,,	0·022	1·66	0·0	$-2·0$
,, minimum rate	4 ,,	0·013	,,	$-1·0$	$-2·5$
Glacier ice B, maximum rate	24 ,,	0·016	2·7	$-2·5$	$-3·5$
Glacier ice C, ,, ...	23 ,,	0·0068	2·55	$-2·5$	$-4·5$
,, minimum rate	3 days	0·0013	,,	$-6·0$	$-9·0$
Glacier ice D, maximum rate	10 mins.	1·88	2·50	$-2·1$	$-2·1$
,, minimum rate	16 hours	0·0054	1·45	$-6·0$	$-10·0$
,, lowest temperature...............	12 ,,	0·0065	,,	$-9·0$	$-10·5$
Icicle, maximum rate	5 ,,	0·0041	2·2	0·0	0·0
,, minimum rate	8 ,,	0·0015	,,	$-0·7$	$-1·7$
Lake ice, parallel columns	7 days	0·00039	2·1	0·0	$-5·5$
,, greater tension	2 ,,	0·00076	2·8	$-4·0$	$-5·5$

Glacier ice G	,,	0·007	,,	,,	,,
Lake ice, parallel to columns { A	3 days	0·0002	3·7	$-3·9$	$-6·0$
Lake ice, parallel to columns { B	,,	0·0012	,,	,,	,,
Lake ice, parallel to columns { C	,,	0·0018	,,	,,	,,

[1] This was a deeper bend than is shown in the figure.

Glacier ice C is the same piece as B, cut rather shorter. The rates of extension given here are of course the mean of the rates observed on the two sides of the bar, which were generally far from being equal. Sometimes the greater speed would fluctuate from one side to the other; in other words, the bar would bend first one way then the other. In other cases one side would always extend faster, *e.g.* in glacier ice D the total extension of one face was 2·9 mm., of the other 9·7 mm. The breaking tension we found in the bath ice to be about 8 kilos per sq. cm., but for obvious reasons we did not care to approach this limit too closely. One curious fact deserves notice. The icicle, which was built up of very small crystals, stretched very slowly; while, on the other hand, the most plastic of our pieces of glacier ice contained one very large crystal. This may have been accidental, or it may have been due to the impurities. The fewer the interfaces the greater the quantity of soluble salts at each.

Let us compare the figures in the table with the plasticity actually observed in glaciers. Heim has collected a number of observations on the increase of velocity from the sides to the centre of a glacier. The most rapid increase he mentions among the Alps is on the Rhone glacier on a line 2300 metres above the top of the ice-fall. At 100 metres from the western bank the mean yearly motion from 1874 to 1880 was 12·9 metres, at 160 metres from the bank it was 43·25 metres This gives an increase of velocity in each metre across the glacier of 0·000058 metre per hour. The stretching involved in this distortion is shown in the paper to be greatest in a direction inclined at 45° to the direction of motion, and then to amount to 0·0029 mm. per hour per length of 10 cm. Hence the plasticity we have found in hand specimens is amply sufficient to account for the distortion of a glacier, even without the aid of crevasses.

It may be said that the term plasticity can not be properly applied to the property of ice that I have described, but there is no other convenient word. Further, it is quite possible that sealing-wax and pitch may be built up of microscopic or ultra-microscopic crystals, and that their plasticity is fundamentally similar to that of ice, the difference being merely one of scale. Helmholtz has suggested somewhere that ice, with its definite and easily ascertainable structure, may furnish the clue to the solution of many difficult problems in the properties of matter.

JAMES C. MCCONNEL.

NOTES.

AT the annual meeting of the Paris Academy of Sciences on December 24, the Bordin Prize, awarded for perfecting the theory of the movement of a solid body, was awarded to Madame Sophia Kovalevsky, a professor at Stockholm University, and a lineal descendant of Matthias Corvinus, King of Hungary from 1458 to 1490. In astronomy, the Valz Prize was awarded to Mr. E. C. Pickering, and the Janssen Prize to Dr. William Huggins. The Montyon physiology prize was divided between Mr. Augustus D. Waller and M. Léon Frédéric.

DR. SCHWEINFURTH has removed his residence from Cairo to Berlin. The German Government has placed at his disposal a house for the accommodation of his African collections, which after his life-time will become the property of the State, but in the meantime remain in his charge, the Government meeting all the expenses of their maintenance.

AT present Dr. Schweinfurth is on his way to Arabia Felix for the purpose of making botanical collections in the mountains of Yemen. Judging from what is known of the limited but extremely peculiar flora of Aden, and from the specimens which Major Hunter, the assistant Resident at Aden, has transmitted to Kew from the interior, the results of Dr. Schweinfurth's explorations are likely to be of the very greatest interest.

A NEW part of the "Scientific Results of Prjevalsky's Expeditions" has just been published by Prof. Hertzenstein. It contains a description of the fishes, and is illustrated by eight plates.

DR. FRANÇOIS, of the Science Faculty of Rennes, has been despatched, by the French Minister of Public Instruction, to Tahiti, to investigate thoroughly corals and coral formations there.

IT is intended that the next general meeting of the Association for the Improvement of Geometrical Teaching shall be held at University College, Gower Street, on January 19, 1889. The morning sitting, at which the Reports of the Council and the Committees will be read, and new officers and members elected, will begin at 11 a.m. After an adjournment for luncheon at 1 p.m., members will reassemble at 2 p.m., when an address will be delivered by Prof. Minchin, of Cooper's Hill, on "The Vices of our Scientific Education."

LAST Friday, Mr. Mundella asked the Chancellor of the Exchequer whether he was able to remove the uncertainty and embarrassment of the provincial Colleges by publishing his scheme for grants in aid; and whether, in consideration of the delay which had already taken place, and the pecuniary position of several Colleges, he would provide that the grants should take effect from January 1 next. In reply, Mr. Goschen said he was not able to make any statement as to the particulars of a scheme for grants in aid to University Colleges in the provinces. In any case it would not be possible for the grants to take effect from January 1 next, as they would be included in the Estimates for the financial year 1889–90, nor could the grants be of such amounts as to retrieve the position of any College in serious financial embarrassment. Government grants, though they would be a valuable addition, could in no case be, and were not intended to be, an effective substitute for local contributions, which must always bear the greater share of the burden. With respect to the scheme in general, Mr. Goschen was anxious to state that any delay which had arisen was due entirely to the number and importance of the subjects competing for the attention of the Government during the session. The Government regarded grants to local Colleges as a step of great importance, and possibly of far-reaching effects. It was absolutely impossible to propose a scheme without the most careful consideration of its bearings, more especially the proportions and the conditions on which any assistance from Imperial funds should be given to local institutions for higher-class education. It was not from any neglect of the matter, but rather from their sense of its extreme importance, that the Government had not been able to formulate their proposal, although they hoped to do so at a very early date.

AT a recent meeting of the Senate of the Sydney University it was announced that the Hon. William Macleay, besides presenting to the University his valuable museum of natural history, which comprises specimens from all the Australian colonies, New Guinea, and the various groups of islands in that quarter of the globe, has also given the sum of £6000 to endow a curatorship for that mu eum.

WE learn from *Science* that Mr. J. W. Osborne, of Washington, the well-known inventor of photo-lithography, has presented to the United States National Museum and to the Art Museum in Boston his large and valuable collection of proofs and specimens illustrative of the development of photo-mechanical printing. All the important and typical processes are fully represented in each by specimens collected by Mr. Osborne in the art centres of Europe and America, and include the works of all who have

in any measure achieved success in the graphic arts. As soon as it can be properly classified, the collection intended for the National Museum will be exhibited in the section of graphic arts. Mr. Osborne's contribution, the Museum authorities assert, has laid a substantial foundation for an exhaustive collection of kindred productions under Government auspices at Washington.

M. BIALOVESKI, of Oostnamenogorsk, Western Siberia, writes to us to suggest that an international journal of geology is greatly needed. Geology, as he points out, is making continual progress, and the number of investigators steadily increases. It is difficult for students to keep up with the advance of the science, since many important communications are contributed to periodicals which are not generally accessible. An international journal, our correspondent thinks, would supply exactly what is wanted. He suggests that it should be edited in some great centre, such as London or Paris, and that the language adopted should be either Latin or English. The question might perhaps be discussed with advantage at the next meeting of the International Geological Congress.

THE geological history of the Caspian depression is the subject of a remarkable article, by N. Andrusoff, in the November number of the *Izvestia* of the Russian Geographical Society. All that is known about the geological structure of the Caspian depression and the surrounding highlands has been turned to account by the author, and he carefully distinguishes between fact and hypothesis. He gives, first, a condensed but well-conceived description of the Caspian Sea; then he analyzes the geological structure of the Great Balkhans in the Transcaspian region, the two parts of the Caucasus—Western and Eastern—and the mountains of the Crimea. He comes to the conclusion that the upheaval of the Crimea-Caucasus-Balkhan system began after the Jurassic period in the Crimea, and was continued through the Chalk period. A considerable raising took place during the earlier parts of the Tertiary period, and the Miocene epoch was characterized by subsidences, especially in the south. Great changes in the relative altitudes of the region followed after the Sarmathian period. Then he sharply separates the two parts of the Caspian Sea—the shallow northern part, and the deep southern part—which originated in different ways, and at different epochs. The history of the basin during the Tertiary period is treated in detail. The want of data for reconstituting it in full is indicated with great precision, but a map is given to show approximately the extensions of the sea during the periods after the middle Pliocene period. Finally, the fauna of the Caspian (a full list of which, including 187 species, is given), and its bearing upon the question, as well as its probable origin, are discussed. The paper is so important that we hope it may soon be translated into English.

THE same number of the *Izvestia* contains a paper on the earthquake of May 27, 1887, at Vyernyi (already described in NATURE); a note on the geodetical connection of Spain with Algeria, by General Stebnitzky (with a map); and a note, by A. Zolotareff, on the surface and population of Persia. Measured on Petermann's map, the surface of Persia appears to be 29,986 square geographical miles, while the probable population is taken at 6,000,000. Two instructions, one for observations on shifting sands, and another for meteorological observations by travellers, are issued in the same number by the Council of the Society.

IN his Annual Report, lately issued, the President of the Johns Hopkins University, Baltimore, presents a very interesting account of the work done at that admirable institution during the past year. The instruction given has never, Dr. Gilman thinks, been more quickening and successful, nor has the progress of literary and scientific undertakings, in charge of the principal teachers, ever been more satisfactory. During the year there has been a noteworthy advance in the facilities for the study of astronomy, theoretical and practical. There has also been a considerable increase in the number of students attending astronomical lectures. In the department of physics the new physical laboratory justifies the expectations which led to its construction; it not only affords increased facilities for instruction, but enables investigations to be carried on with greater efficiency. The only cause for anxiety with regard to this University is the loss of income from the stocks which were given to it by its founder. Strenuous efforts are about to be made to provide new sources of revenue, and there ought to be no doubt as to their success.

THE peninsula of Florida contains innumerable isolated ponds varying from a few square rods to many square miles in area. Many of these are simple hollows filled with rain-water, without any connection with other waters. Some of them are on high ground, where no flood can establish temporary connection with other waters, through which fish might be admitted. The smaller ones often dry up entirely in seasons of drought, yet when filled with water they do not seem to be behind their neighbours in population. They all swarm with fish. For instance, at Orange Heights, in Eastern Alachua County, which is one of the most elevated regions of the State, as is plainly shown by the radiating streams which rise in that vicinity, there is a small pond on the top of the highest elevation in all that region. Mr. Charles B. Palmer, who records these facts in *Science*, says he has twice known this pond to be dry, yet it now contains an abundance of small fish. "How have they been preserved from destruction," asks Mr. Palmer, "and whence came the original stock?"

THE *Times* says that the collection of *Salmonidæ* ova has been made on a large scale this season at the Midland Counties Fish Culture Establishment, Malvern Wells, and Mr. William Burgess, its founder and proprietor, has laid down for incubation large quantities of eggs. Arrangements have been made for rearing such an extraordinary number of fish that the hatcheries are being taxed to their uttermost. Eggs will be received and hatched out, free of charge, for public bodies. The acclimatization of the American whitefish, *Coregonus albus*, is to be attempted by Mr. Burgess, with the co-operation of the United States Fish Commissioners, who have expressed their willingness to forward consignments of the ova of this valuable food-fish, which is held in high favour in America. In order to carry their naturalization to a successful issue, special habitats have been provided of great size and depth, while all that is necessary to their existence has been furnished. The operations of last season have resulted in an extensive distribution of fish in various lakes and other waters in this country. Coarse fish, such as perch, tench, carp, and roach, have been propagated artificially by Mr. Burgess with a success that has induced him to increase his labours in this direction by enlarging his establishment.

THE Minister for Agriculture in Victoria announces that the Government will probably select some land on which to build an institution where attention will be paid to vine-growing solely, under the control of the Central Board of Viticulture.

THE northern limits of the culture of the silkworm are being steadily extended. Experiments made last summer at Astrakhan showed that it could easily be carried on at the mouth of the Volga. Notwithstanding the age of the mulberry-trees, which were planted at Astrakhan thirty-five years since, the results of the experiments proved satisfactory, and 20,000 cocoons were received this year.

WE have on several occasions drawn attention to the progress of the meteorological service in Queensland since Mr. C. L.

Wragge undertook its reorganization about two years ago. We learn, however, from the Adelaide *Evening Journal*, that at the recent Meteorological Conference at Melbourne serious objections were made to the issue of intercolonial weather forecasts from the central office at Brisbane, and that a resolution was passed to the effect that no forecast should be telegraphed from one colony to another. It is evident that if this proposal were carried out, it would practically check the advance in weather prediction which it has been Mr. Wragge's aim to foster, and the suggested alteration was, naturally, strenuously opposed by Mr. Wragge. The success of the service in Queensland is greatly due to the co-operation of the Post and Telegraph Departments, observations being taken at every station in the colony. Mr. Wragge proposes to establish other stations in the far north and west districts, and to examine the climatological factors of the stations generally, with the view of the cultivation of wheat in Central Queensland as profitably as in South Australia.

We have received from Prof. C. Wagner, Director of the Observatory of Kremsmünster, a discussion of the rainfall and thunderstorms at that place; the paper contains some interesting results, especially with regard to thunderstorms. The Observatory is situated in lat. 48° 4′ N., and long. 14° 8′ E. (in Austria), and possesses a very long series of observations, dating back to 1763. The older series, from 1763–1851, have been discussed in vol. i. of the Vienna *Jahrbuch*, 1854. The first rain-gauge was erected in April 1820, so that Prof. Wagner is able to publish the observations for each month of the years 1821–87, one of the longest periods existing, yet he finds that the period is too short to determine with accuracy the range of the rainfall for single months. The average yearly amount is 38·5 inches. The greatest falls occur in July, the least in February, and there is a second maximum in November. It would appear that the rainfall has increased latterly: dividing the series into two periods, it is found that the average number of rainy days from 1821 to 1850 is 123·4, and from 1851 to 1887, 142·8 days. The thunderstorm observations are given for each month since 1802. The average number of storms yearly is 35; they occur mostly in June and July. During the whole eighty-six years only one storm occurred in December. The author gives the daily and yearly range according to the direction of the storms, and also the daily range without reference to direction. These tables show a regular period of frequency. The maximum occurs from 4h.–5h. p.m., the number then decreases until 7h. p.m., and from 7h.–8h. there is a second maximum. A third maximum also occurs from 1h.–2h. a.m. He also investigates the possible influence of the moon on the frequency of the storms, and finds (as has before been observed at Prague) that a maximum occurs at the times of the full moon and last quarter. The same fact shows itself when the series is divided into two sets.

A shock of earthquake was felt at Tashkent, on November 28, at 11.40 a.m.

The Caucasian papers give the following details as to the earthquakes which were felt at Kars and the neighbouring region in September last. The first shock was felt at Kars on September 23, at 3.25 a.m.; it reached its maximum intensity on the high left bank of the Kars River, where several crevices appeared in the barracks of Mukhlis, while on the right bank of the river, which is flat and low, it was felt with much less intensity. The direction of the earthquake was from south-west to north-east. The second and third shocks were felt at 6 and at 9.30 a.m. respectively. They were feeble, and were followed, at 3.20 p.m., by a much stronger shock, which lasted for about five seconds, and had the same direction. A new shock followed at 8.25 p.m.; it had the same direction, but the undulatory movement of the soil was also accompanied by vertical shocks. The direction of the undulatory movement of the soil seems to have taken a more northern direction in the next shock, which was felt at 11.20 p.m. Several shocks followed during the night and the next morning, and a very strong shock, lasting for about ten seconds, was felt on the next day at 2.35 p.m.; its direction was, first, towards the north-north-east. A vertical shock soon followed. Crevices appeared in most buildings, and several houses in the Armenian village Tchighirgan were destroyed. Strong shocks followed at 10.5 and at midnight. On September 13, the earthquake was continued by several slight shocks and a strong one at 9 a.m.; next day, there was a slight shock at 11.25 a.m. This was almost vertical; but an improvised seismometer shows a deflection of the point towards the north. In the Ghel division of the Ardahan district, the same shocks were felt, and had more serious consequences. In the villages of Altun-bulack, Hoshtulbent, Plor-mori, Mehkerek, Shaki, Tondash, Kalpikor, and Kundun-su, most houses were destroyed. Five persons were killed.

At the last meeting, November 16, of the Russian Geographical Society, D. N. Ostrovski made an interesting communication upon the Lapps. Their numbers are estimated at 28,000, of whom 25,000 are living in the territories of Sweden and Norway, and the remainder in Russia and Finland. Almost all the Lapps who live in Sweden are nomads; those who stay in Norway are half nomadic. Those of Finland are all settled, and some of them even have no reindeer; a school was opened for them last year. Sea fisheries are their chief occupation. At the end of the summer they fish in the lakes in the interior of the Koha peninsula, and in the winter they stay in their small houses (*tups*) in the neighbourhood of the marshes covered with moss, where their reindeer obtain food. Their settlements spread in Norway only as far as the 62nd degree of latitude, but in Finland they go as far north as Lake Enare. Their former dwelling-places were farther south, but they were compelled to migrate northwards by the Finns, who steadily extend their settlements in this direction, clear the forests, and take the best grazing-grounds. The folk-lore of the Lapps is full of traditions about their struggles with the Finns. The opinion formerly entertained as to their dying out is not quite exact, although it is true that the Lapps are being steadily absorbed by the Finns. A rich collection of photographs, and samples of various domestic implements, and of the dress of the Lapps, have been brought in by M. Ostrovski.

A correspondent, writing from Glasgow, describes the following incident, an account of which was given to him by an eye-witness. It occurred at Dumbarton on Friday, the 17th inst. A hare came across the marsh or common there, on to the embankment of the River Leven, near the slaughter-house at present being erected. At the same time a man came along the embankment of the river, making for the new building. The hare, seeing her escape cut off by the man on one side, and by the workmen at the building on the other (she might have escaped across the marsh, the way by which she came, as she did not seem to be pursued), took to the water and swam across. But, unfortunately, at the opposite side her landing was barred by another man. When she saw the danger, she turned, and made for the point she came from, but the man walking along the embankment had by this time come up, and was awaiting her return. On approaching the bank, and seeing that escape was hopeless, the hare gave up, and made no further effort. The man then stepped into the river, and getting hold of her, extinguished any life that was left. "Is it a common occurrence," asks our correspondent, "for the hare to take to the water? I never read or heard of it before."

Dr. Croll, F.R.S., has just completed a volume on "Stellar Evolution and its relations to Geological Time." It will be published immediately.

A THIRD edition of the well-known "Orient Line Guide," by the Rev. W. J. Loftie, has been issued by Messrs. Sampson Low. The abandonment of the Cape route, as the editor points out, has left room for expanded notices of places hardly mentioned in former editions. The whole plan of the volume has accordingly been changed. In its present form the work contains a continuous narrative of a voyage from London to Australia, broken only by a journey home from Naples, and by various interesting excursions. In the accomplishment of this difficult task Mr. Loftie has received aid from several eminent writers, whose contributions add largely to the value of the book.

THE "Record of the Excursions of the Geologists' Association—1860 to 1884," which has been prepared by Mr. T. V. Holmes, F.G.S., is now ready for the press, but it will not be printed until a sufficient number of subscriptions have been promised. The work will consist of over 500 pages, and contain accounts of all the sections and districts visited by the Association down to the end of 1884, with the illustrations (sections, &c.), which have from time to time appeared in the Circulars and Proceedings.

THE Gamble Prize Medal at Girton College has been awarded to Miss Marion Greenwood, certificated student of Girton College, for an essay on "The Digestive Process in certain Simple Organisms—Amœba, Actinosphærium, and Hydra."

"M. F." has sent to the *Times* a list of sixty-nine different species of wild flowers which have been found in blossom during the present month in the neighbourhood of Hardingham, Norfolk. "This fact," he says, "is no doubt partly accounted for by the unusual mildness of the season, but it also speaks well for the climate of the eastern counties, which has been given, I think, a worse character than it deserves. I can vouch for all the flowers being genuinely wild, as they have, without exception, been gathered by my sisters or myself. Among the most remarkable are poppy, white ox-eye, strawberry, pimpernel, primrose, and field scabious."

THE Report of the Director of the Colombo Museum for the past year says that the Reports which have been written by him on the collection of snakes, lizards, and frogs have been printed, and that on the birds is in the press. The Report on the monitors and skinks is finished, but is yet in manuscript. A Report has also been written on the butterflies, to the end of Nymphalidæ, and on the moths to the end of Bombycides. These two latter are not to be printed for the present, for it is hoped that the notes will be supplemented; and it is suggested that the classification and nomenclature be made the same as those adopted in De Nicéville's book on the butterflies of India, which will soon be published. The difficulties met by the Director in the formation of a collection have been many. The entomological specimens have been with difficulty preserved from the attacks of fungus and mites. A strong solution of creosote and benzene was found to be perfectly useless, but sponges soaked in citronella oil and placed in the cases have been fairly successful. At present, the mode of treatment in the Museum is as follows. When the insect is removed from the setting-board, its body is bathed in benzene, and if this does not keep the mites away, the bath is renewed; in case of fungus, the insect is touched with a solution of carbolic acid in benzene, and, as has been just mentioned, sponges soaked in the best citronella oil are always kept in the cases. That this method is effective is shown by the fact that there are specimens in the collections for the past fifteen or twenty years which have been treated in this way, and are now free from attacks. During the past year a great improvement has been made in the transportation of insects to the Museum. A layer of naphthaline is put at the bottom of tins, such as are used for tobacco and butter, then a layer of cotton-wool is spread over this, then a layer of insects, and so on till the tin is filled with alternate layers of wool and insects. By this means the insects are kept relaxed for upwards of a fortnight, and there is thus time to despatch them from any part of the island to Colombo. This plan is far superior to that formerly in use by insect-boxes, setting-boards, and all the other necessary apparatus which were carried from place to place at great trouble and expense. Mr. Haly hopes to establish stations throughout the island, from which insects may be sent from time to time to Colombo. In searching for marine fauna, Mr. Haly found that the dredge employed by naturalists in Europe is almost useless in Ceylonese boats; but one similar to that used by Prof. Agassiz in the Gulf of Mexico, with lighter arms than the common European one, and with perfectly flat scrapers, answered very well. Some fossil crabs from Kuchavelli have also been collected during the past year. In other departments the Museum has been enriched by various rare and interesting specimens.

THE additions to the Zoological Society's Gardens during the past week include a Ring-tailed Coati (*Nasua rufa*) from Pernambuco, presented by Mr. J. W. Bell; a Blue-fronted Amazon (*Chrysotis æstiva*) from Brazil, presented by Miss Hayes; three Common Partridges (*Perdix cinerea*), British, presented by the Rev. F. T. Scott; two Moorish Geckos (*Tarentola mauritanica*) from the South of France, presented by Masters F. and O. Warburg; an Egyptian Cat (*Felis chaus*), a Paradoxure (*Paradoxurus* sp. inc.) from India (?), two Long-tailed Fowls (*Gallus domesticus* var.) from Japan, deposited; a Yellow-footed Rock Kangaroo (*Petrogale xanthopus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

MADRAS MERIDIAN CIRCLE OBSERVATIONS, 1865, 1866, 1867.—We have recently received from the Director of the Madras Observatory, the "Results of the Observations of the Fixed Stars made with the Meridian Circle at the Government Observatory, Madras, in the Years 1865, 1866, and 1867," and are glad to see by its appearance that Mr. Pogson is continuing his efforts to remedy the most deplorable delay which has attended the publication of the observations made under his care. The present volume is in continuation of the one which appeared a year and a half ago, and which contained the results for the years 1862–64. The instrument employed and the class of objects observed were the same as in the three earlier years; the objects selected being the moon and moon culminators, Mars and companion-stars, minor planets, the brighter stars down to the fifth magnitude, and as many unnamed stars as possible below 120° N.P.D., and not fainter than the eighth magnitude. The present and preceding volumes have been confined to stellar observations, and these are given separately for each year in the twofold form of star-ledger and annual catalogue. The Star Catalogue will follow at the conclusion of the publication of the results for the separate years, and it is hoped that it may be succeeded by a volume of planetary and cometary results. Very little interest or value now attaches to these sadly overdue volumes of annual results, except as an indication that the evil of delayed publication is now really recognized, and as affording a hope that the one really useful work, the General Star Catalogue, may soon appear. It is but due to Mr. Pogson, however, to remember that his position is one which has presented many difficulties, seeing that he had, as he states in the present volume, "no European assistance, and too inadequate a staff of natives even to admit of duplicate calculations."

COMET 1888 *e* (BARNARD, SEPTEMBER 2).—One of the positions from which Dr. Becker computed the hyperbolic orbit for this comet (NATURE, November 29, p. 114) has been found to be in error, as compared with neighbouring observations by as much as 13″ in declination, and fresh normal places having been formed a parabola is found to satisfy them well The following

elements and ephemeris are by Dr. A. Berberich (*Astr. Nach.*, No. 2867):—

$$T = 1889 \text{ January } 31{\cdot}23814 \text{ Berlin M.T.}$$

$$\left.\begin{aligned} \omega &= 340^\circ\ 28'\ 1''{\cdot}5 \\ \Omega &= 357\ 24\ 48{\cdot}8 \\ \iota &= 166\ 22\ 11{\cdot}2 \end{aligned}\right\} \text{Mean Eq. } 1888{\cdot}0.$$

$$\log q = 0{\cdot}258900$$

Ephemeris for Berlin Midnight.

1889.	R.A. h. m. s.	Decl. ° ′	Log *r*.	Log Δ.	Brightness.
Jan. 0	0 19 36	7 19·5 S.	0·2688	0·2403	5·5
2	0 15 48	7 13·2			
4	0 12 20	7 6·5	0·2664	0·2633	5·0

12	0 1 6	6 35·8	0 2626	0·3053	4·2
14	23 58 51	6 27·5			
16	23 56 48	6 19·0 S.	0·2612	0·3242	3·9

The brightness at discovery is taken as unity.

Dr. Copeland (*Dun Echt Circular*, No. 165) anticipates that, though the computed brightness is decreasing, the intrinsic brightness will increase until the beginning of February. Dr. Copeland also announced, in a paper read before the Royal Astronomical Society at its last meeting, that the spectrum of the carbon bands had become decidedly more conspicuous lately than when the spectrum of the comet was first observed.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 *DECEMBER* 30—1889 *JANUARY* 5.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on December 30

Sun rises, 8h. 8m.; souths, 12h. 3m. 3·2s.; sets, 15h. 58m.: right asc. on meridian, 18h. 40·5m.; decl. 23° 8′ S. Sidereal Time at Sunset, 22h. 36m.

Moon (New on January 1, 21h.) rises, 4h. 55m.; souths, 9h. 36m.; sets, 14h. 9m.: right asc. on meridian, 16h. 13·1m.; decl. 17° 16′ S.

Planet.	Rises. h. m.	Souths. h. m.	Sets. h. m.	Right asc. on meridian. h. m.	Declination on meridian. ° ′

GEOGRAPHICAL NOTES.

IN a paper (accompanied by a map) in the last number of the Proceedings of the Royal Geographical Society, we are told by the author, Captain Langen, that the Key, or Ké, Islands derive their name from the native word Ké (pron. Kay), which signifies "What do you say?" The native tradition runs that when Macassar traders first landed there, and inquired in the Malay tongue after the name of the land they had set foot on, the Key natives answered "Kay?" which expression was mistaken by the questioners for the name of the islands; and under this name, which has been changed into "Key," or "Ké," we find them on charts of the East Indian Archipelago. The islands are very incorrectly laid down on all nautical charts, and Captain Langen's brother has taken great pains in drawing up a map according to his own survey, which is given in illustration of the paper. The group consists of two larger islands, of which the westerly one bears the name of Nuhu-roa, or Little Key, and the easterly one Ju-ud, or Great Key, surrounded by a number of smaller islands. There is no doubt that Great Key is geologically much older than Little Key and the other surrounding islands; it possesses elevations of from 2000 to 3000 feet, whilst Little Key and the other islands are very low. Great Key principally consists of a rocky and volcanic formation, whereas Little Key and the surrounding islands are formed of coral and interveined by flint and quartz. The traveller will find on the highest inland elevations of Little Key (200 feet) shells of various species, greatly damaged through long exposure to wind and weather. About thirty-five years ago, according to the most reliable chiefs, Little Key was raised out of the sea during the shocks of a severe earthquake, attended by a tidal wave; since then no earthquakes occurred until 1884, in the month of April. The members of the European settlement report that the day opened sultry and stifling, the sun shone till about 9 a.m., when the sky became overcast, and at 10 a.m. the first shock was felt, which caused our saw-mill, then in course of erection, to sway to and fro. No sooner had the workmen felt this first shock than they rushed out of the building, and after a short lapse of time two more slight shocks were felt, but fortunately without doing any serious damage. About half an hour's walk eastward from Doelah, is an extinct crater, filled with fresh water, of a great depth, and of a very dark blue colour. Every island belonging to the Key group is covered, down to the water's edge, with dense tropical jungle, gigantic creepers winding themselves from one tree to another, thus forming a close network and great impediment to travelling. These forests contain choice kinds of timber, which formed one of the principal inducements for the establishment of the present German colony.

THE Hon. F. T. Gregory, the well-known Australian traveller, died some weeks ago at his residence in Queensland. He was one of the earliest settlers in Western Australia, where he remained for upwards of thirty years. So far back as 1846, he headed an Expedition to explore the country around the Swan River, and in 1857 he was engaged in exploring the northern coast of Australia. In this latter journey he discovered the Ashburton and Fortescue Rivers. He also drew up a geological map of Western Australia. He went from the latter colony to

Queensland, where he remained till his death, occupying many public posts, the last that he filled being that of Postmaster-General. Some years ago he received the gold medal of the Royal Geographical Society.

THE FARMER'S GUIDE TO MANURING.[1]

THE low average yield of wheat in Australia, of some 8 bushels per acre, appears to be due in a great measure to defective cultivation. Victoria, however, enjoys a more promising soil, and in the little pamphlet before us, 15 to 18 bushels of barley are given as probable yields of this cereal on unmanured land. It has frequently been observed that the most worn out soils respond with the greatest effect to the application of fertilizers, and in agreement with this principle we find that by the use of artificial manures, the 15 bushels is converted into 50, and the 18 bushels into 47. Such results could not happen upon a well-cultivated English farm. The law of the land with reference to its condition appears to be that the higher it is in degree of fertility the greater is the difficulty of producing further increments of produce. This is really a *crux* in English farming. Every succeeding bushel is wrung out of the soil at a greater cost than the last, and this constitutes one of the most difficult problems in connection with high cultivation. Now, in a country like Australia, or even like many of the States of America, this difficulty does not as yet exist, and the land is able, according to Mr. Pearson, to answer with extraordinary alacrity to the application of fertilizers. This is the only way in which we can account for the statement made in the pamphlet in question, and for the fact that it is thought worthy of being published by the Government at Melbourne. Profits of 145 and of 215 per cent. from artificial dressings are somewhat startling, but we are not disposed to dispute their possibility. Such results are not entirely beyond our experience, on worn out soils, when the crop is apparently entirely due to applications of dressings. We have seen on such soils a miserable crop on the portion left unmanured and a good crop on the plots liberally treated, and this, of course, is parallel to the cases cited in Victoria.

The merit in Mr. Pearson's suggestions lies not so much in their originality as in their practical utility. We are familiar with the wants of plants for nitrogen, potash, lime, and phosphoric acid; and there is nothing new in the idea of a "complete manure." But the suggestion that manures should be carefully compounded for experimental purposes, properly labelled, and sent out by well-known firms, subject to Government control, is, if not novel, at least enterprising. These manures are labelled as follows: C. for cereals, L. for Leguminosæ, R. for root crops; and are accompanied with simple directions for their proper application.

Plots one-fortieth of an acre in extent are recommended, and full directions for their measurement are supplied thus:—

If the lands measured from the middle of one furrow to the middle of the next be	9 feet wide,	the length taken should be 121 feet.
	10 ,,	,, ,, ,, ,, ,, 109 ,,
	11 ,,	,, ,, ,, ,, ,, 99 ,,
	12 ,,	,, ,, ,, ,, ,, 91 ,,
	13 ,,	,, ,, ,, ,, ,, 84 ,,
	15 links	,, ,, ,, ,, 1 chain 67 links.
	16 ,,	,, ,, ,, ,, 1 ,, 56 ,,
	17 ,,	,, ,, ,, ,, 1 ,, 47 ,,
	&c.,	&c., &c.

Nothing could well be simpler or more calculated to enlist the sympathies of agriculturists. With properly mixed, weighed, and labelled bags, neatly turned out by good firms, and controlled in composition by the Agricultural Department, and with simple rules for measuring off plots, and with directions for carrying out these simple experiments—what more could a farmer want?

In conclusion, farmers, and all engaged in cultivating the ground, are earnestly recommended to give a trial to this system of test plots. By making use of them they can see from season to season what manure produces the best effect upon their land, and instead of working in the dark they will know exactly how they are laying out their money.

The question is, Will they avail themselves of the offer of the Department, and the assistance promised in carrying out the instructions? Probably not; but one thing is certain—that if the farmers of Australia and America once grasp the idea of intensive culture as opposed to their present system of extensve cultivation, and go in for producing high yields per acre, the promised relief from foreign competition in wheat-growing must be indefinitely postponed. We look forward with some interest to learn how far the efforts of Mr. Pearson and the Minister of Agriculture will be seconded by the farmers of Victoria.

JOHN WRIGHTSON.

[1] "The Farmer's Guide to Manuring," by A. N. Pearson. Printed by order of the Hon. J. L. Dow, Minister of Agriculture, by authority. (Melbourne: Government Printing Office, 1888.)

ON THE DISCOVERY OF THE OLENELLUS FAUNA IN THE LOWER CAMBRIAN ROCKS OF BRITAIN.

THE brief paper on the "Stratigraphical Succession of the Cambrian Faunas in North America," communicated to NATURE (vol. xxxviii. p. 551), will have been read by British students of the geology of the Lower Palæozoic rocks with especial interest and satisfaction, as it puts an end to a controversy between European and American geologists, and brings into harmony the sequence and palæontology of the Cambrian faunas on both sides of the Atlantic.

The remarkable fauna of the *Olenellus*, or lowest Cambrian zones, originally discovered in America, by Dr. Emmons, in 1844, was first recognized in Europe by the late Dr. Linnarsson in 1871, in the basal beds of the Cambrian, near Lake Miösen in Norway; but its typical genus, *Olenellus*, was then referred by him to the allied but more recent *Paradoxides*. This reference was corrected by Prof. Brögger in 1875, and the various brilliant papers on the primordial formations by this author have given the *Olenellus* fauna a marked and peculiar interest. In 1882, Linnarsson next made known the existence of the *Olenellus* fauna in Scania, at the base of the Swedish Cambrian. In 1866 the same fauna was detected by Mickwitz in the Lower Cambrian of Russia (Esthonia), and this Russian fauna has been lately figured and described in detail by Dr. Schmidt, of St. Petersburg. Still more recently (December 1877), Dr. Holm has signalized the existence of the *Olenellus* fauna in the Cambrian of Lapland, where it was detected by Mörtsell in 1855. Thus the existence of this peculiar fossil-group (the oldest well-marked fauna yet recognized by geologists), in the Lower Cambrian rocks, has been already demonstrated in three main regions: (1) in the region of the Rocky Mountains; (2) in the region of North-East America; and (3) in the region drained by the Baltic Sea. But, up to the present time, no notice of its presence has been recorded from the British Islands, where the oldest fauna hitherto described is that of the overlying *Paradoxides* zones, or Middle Cambrian formation.

The existence of traces of the *Olenellus* fauna in the Cambrian rocks of the west of England, has, however, been known to myself for some time. The first recognizable fragments of the characteristic genus *Olenellus* were detected by me on the flanks of Caer Caradoc, in Shropshire, in 1885, but they were too imperfect for description. During the summers of 1887 and 1888, Mr. H. Keeping, who has been collecting under my direction the characteristic fossils of the Lower Palæozoic rocks of the district for the Woodwardian Museum, has obtained a sufficiency of fragments to enable us to recognize a large and well-marked species of *Olenellus*. This species possesses characters apparently intermediate between the European form *Olenellus Kjerulfi* (Linnarsson), and the undescribed American form *Olenellus Bröggeri* (Walcott, *MS.*); but it is so closely allied to the last-named species, that I prefer to await the publication of Walcott's diagnosis of his form before publishing its specific description. I have provisionally named it *Olenellus Callavei*, after Dr. C. Callaway, F.G.S., who was the first to demonstrate the presence of fossiliferous Cambrian rocks in this Shropshire district, and to collect Cambrian fossils from the strata under notice.

The Lower Cambrian or *Olenellus* formation of this Shropshire area consists of two main members: (*a*) the basal Quartzite of Lawrence Hill and Caer Caradoc, and (*b*) an overlying green sandstone, the Comley Sandstone (Hollybush Sandstone of Dr. Callaway). This formation follows unconformably upon the so-called Uriconian volcanic rocks of the district, and occurs in many localities, as at Lilleshall, the Wrekin, Caer Caradoc, Cardington, &c. In mapping this formation through the district, I find that its fossils are mainly confined to the sandstones, and to certain calcareous and phosphatic beds within them. In addition

to *Olenellus*, we find in various localities such characteristic Lower Cambrian forms as *Kutorgina*, *Mickwitzia* (?), and *Acrothele*. The strata of this *Olenellus* zone are succeeded irregularly by (usually faulted against) the Shineton Shales of Dr. Callaway, which are known to contain in their highest zones an abundant fauna of Tremadoc (Upper Cambrian) age. No trace of the intermediate or *Paradoxides* fauna has yet been detected.

Although this discovery has been well known to my fellow-workers among the Lower Palæozoic rocks, I have refrained from placing it upon record until my identifications had been confirmed by foreign palæontologists familiar with the *Olenellus* fauna abroad. As the specimens I exhibited at the London meeting of the Geological Congress were unhesitatingly referred to the typical *Olenellus* fauna both by Mr. Walcott and Dr. Schmidt, there is no longer any excuse for withholding its publication. The necessary geological and palæontological details will appear in due course, but as these new facts may, it is to be hoped, lead geologists in the meantime to a renewed investigation of the strata and fossils of the more ancient formations, it will perhaps be of service to point out that the detection of this lowest Cambrian fauna in beds superior to the Wrekin quartzite opens out a fresh series of problems in British geology. Thus the presence of *Olenellus* in these beds appears at first sight to fix distinctly the pre-Cambrian age of the so-called Uriconian rocks of the Wrekin and their British equivalents, and even to render the pre-Cambrian age of the Longmyndian a matter of fair probability. With the Longmyndian would possibly go the Torridon rocks of North-West Scotland, the schists of St. Lo in France, the Sparagmites of Norway, &c. Again, if the Wrekin quartzite is, as has been more than once suggested, the extension of that of Nuneaton and Durness, then our so-called Upper Cambrian of the Malverns, Central England, and North-West Scotland may be in reality a greatly attenuated representative of the Cambrian system in general, the British extension of the remarkably attenuated Proterozoic formations of Western Europe. If so, this attenuated Cambrian may eventually be mapped as patches of an originally fairly continuous band, ranging from Lapland, through Esthonia, Scania, Norway, Scotland, Central England, France, and Spain, to the Island of Sardinia. The Sardinian and Durness formations, on the extreme south-east and north-west points of this line, would agree in lithology, age, and fauna, both ranging from the base of the Cambrian up to the lowest zones of the Ordovician. It should be carefully borne in mind, however, that in the present state of our knowledge these suggestions must be regarded simply as constituting a provisional working hypothesis, of service mainly as a stimulus to future discussion, investigation, discovery, and correction.

Grouping together, however, such facts as are already known, and employing Mr. Walcott's nomenclature, we are now able to parallel his American tables by the following European equivalents:—

TABLE I.—*North-Western Europe.*

		Norway.	Sweden.	Esthonia.	Lapland.

C. LAPWORTH.

THE FORESTS OF UPPER BURMAH.

MR. H. C. HILL, the Conservator of the Forests of Upper Burmah, in his Report for the past year—that is, the first year of the existence of a Forest Department in that territory—says that even in that short time a great advance has been made in the protection of forests. Though the Secretary of State sanctioned the appointment of a staff of two conservators and nineteen assistant conservators, and the Indian Government decided that for the present one conservator and fifteen assistants should be appointed, yet the staff in July numbered no more than eleven. The addition of two more is, however, promised at an early date. The work done by this small staff has been very difficult. The areas are enormous, a division averaging about 4000 square miles, the forest land of that tract being from one-third to one-half of the area. Besides, every opposition has been put in the way of the work of the Department by the natives, who have been accustomed in the past to cut the forest timber as they liked. And so it became necessary to send armed escorts with the officers. The Inspector-General's suggestion that a sufficiently strong force of armed men should be organized to protect the forest officers was not acted on. A body of about two hundred police are now constantly engaged in this service. Occasionally difficulties have cropped up, especially when long marches were to be made, but on the whole the present system has worked well. The knowledge that Dacoits might be met with at any turn has to some extent hampered the operations of the forest officials. From the reckless cutting of timber in the past it is probable that the supply in accessible forests will prove smaller than was anticipated. No actual demarcation has as yet taken place, but 5560 acres in the Ruby Mine district have been inspected, and a further area of 2440 acres has been described as suitable for reserve land. During the year fifty-seven persons were convicted of various offences against the forest regulations. Nurseries have been established at Bernardymo and Mogouk, where besides the work done in forest trees, 500 European grafted fruit trees were planted, and of these 149 grew, including pears, apples, peaches, apricots, and plums. One great difficulty has been the disputes between the original lessees of the Royal forests and the present Forest Department. The Government offer has been accepted by the Bombay Burmah Corporation, but other lessees have not yet assented to the terms. The Government propose to continue the rights under the various leases to the holders under new agreements, substituting a system of payment on the timber actually extracted for the yearly lump-sum payments, and enforcing the rules and regulations as regards girdling, felling of green teak, and all other matters connected with the girdling of the forests. The effect of the war can be seen in the returns of the amount of timber felled. Thus the Bombay Burmah Corporation extracted from the Pyinmana forests in 1885, 63,000 tons; in 1886, 18,000 tons; in 1887, 26,000 tons. There has been a serious loss to the forest revenue in the past year by the wholesale plundering of unmarked timber by local traders. After passing through various hands, this timber finally reached a revenue station, where it was passed into the market centres on payment of the local duty.

THE COCOA-NUT PALM.

THE Government Press at Madras recently issued "A Monograph on the Cocoa-nut Palm, or *Cocos nucifera*," by Dr. John Short, which, the introduction tells us, was written at the request of the Director of Revenue, Settlement, and Agriculture. The author begins by pointing out the area of distribution of the cocoa-nut tree. It is indigenous in the East, and is now largely cultivated on the coasts of India and Ceylon, and in the islands of the Eastern Archipelago. There are as many as twenty millions in the south-west of Ceylon. The palm frequently grows wild in distant and isolated islands, whither the germ has been borne by the sea, the thick fibrous padding around the nut protecting it from the action of the water. So we constantly see that coral reefs, as soon as they make their appearance above the surface of the water, are taken possession of by these trees. The sea-shore is the home of the palm; it grows quite down to the water's edge, and is in many places constantly washed by the waves. Thus, along the Brazilian coast for a distance of nearly 280 miles, from the River San Francisco to the bar of Mamanguape, these trees extend. We also, however, find them far inland, and at the height of several thousand feet above the level of the sea. At Bangalore they flourish and produce fruit in abundance at a height of 3000 feet above the sea-level. From a dietetical and economical point of view, the cocoa-nut palm is a most valuable plant; sugar, starch, oil, wax, wine, resin, astringent matters, and edible fruits are its gifts to man. An alluvial or loamy soil is the most suitable for planting it, and no more than 80 plants an acre should be planted to get the maximum amount of fruit possible. Nuts obtainable from trees of from fifteen to thirty years old are the best for planting. There are numerous varieties of this tree, there being as many as thirty in Travancore alone. One dwarf variety bears fruit when it is only 2 feet in height. Toddy is the sap of the cocoa-nut palm, and when the toddy-drawer wishes to get out the sap of the tree, he binds the flower spathe tightly with fibres of the tree, and beats it twice a day for three or four days with a short stick. The top is then sliced, and as soon as the sap begins to flow, a vessel, either earthen or made of bamboo, is tied to the spathe to receive the sap. The spathe is kept bleeding by making a fresh wound in it each day. The fluid, when fresh, has a pleasant taste, and is slightly aperient. When kept for a few hours, it ferments and becomes somewhat intoxicating, and it may then be distilled into spirits or vinegar. With bakers it takes the place of yeast. The quantity of toddy taken out varies with the age and locality of the spathe, but the average quantity obtained for two or three weeks is three or four quarts every twenty-four hours. The liquid is also boiled down into a coarse kind of sugar called jaggery, which is either converted into molasses, or refined before fermentation sets in into white or brown sugar. In some places the occupation of toddy-drawer is an hereditary one. Their mode of work is very simple, but is extremely dangerous. A thong made of bullock or buffalo hide, from 3 to 6 inches in width, and long enough to surround the tree and the body of the climber, is fastened with a peculiar kind of knot. The worker then stretches the thong to its utmost by throwing his whole weight on it, and draws up his legs. He has a ring of rope of palmyra fibres around his insteps, which allows him to grasp the tree between his heels. While his left hand is pressed against the trunk he shifts the thong up the tree with his right and draws his body up with it.

"Cocoa-nut day" is celebrated in most parts of India during the full moon in August. On that day numbers of nuts are thrown into the sea as an offering to the Hindu gods. Occasionally one meets with deformed nuts, consisting of the husk with small deformed nuts having no kernel inside. The natives attribute this blighting of the fruit to the tree frog (*Polypedates maculatus*), which, by smelling the flower, can prevent the fruit from coming to maturity. The kernel of the nut is frequently made into ornaments for the hair, or necklaces. The plants, Dr. Short says, are subject to disease from two opposite causes: first, from too much moisture, as in swampy soils, where the fronds are usually small and ill-formed, and the fruit scarce; secondly, from lack of moisture, where the soil is hard and dry, the sap-bearing vessels shrink and the plant perishes. Amongst the insects and animals destructive to the palm may be mentioned the *Calandra palmarum*, or cocoa-nut weevil, which eats its way into the heart of the tree, and forms its cocoon there; the *Butocera rubus*, or cocoa-nut beetle; the *Oryctis rhinocera*, or rhinoceros beetle; the *Pteromyes petaurista*, or flying squirrel; the *Sciurus palmarum*, or common striped palm squirrel; the *Pteropus edwardsi*, or flying fox; and the *Paradoxurus musanga*, or tree-dog. The rat family is very destructive, particularly in the Laccadives. It is exceedingly difficult to get at these rats, they make to themselves so many hiding-places amongst the trees. Rat hunts are, however, occasionally got up, and to these all the inhabitants turn out with sticks and poles. While some of the hunters climb the trees and drive out the rats, the rest surround the trunks and kill the animals as they rush down. On some of these occasions thousands of rats are killed. The people, being Mohammedans, cannot be induced to keep dogs. It only remains to add that there are ten excellent illustrations in this monograph.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following open scholarships and exhibitions were awarded at St. John's College, in mathematics and natural science, on December 21:—

Foundation Scholarships: Hough, Christ's Hospital (£80); Pocklington, Yorkshire College (£80); Chevalier, Cowper Street School (£60); Rosenberg, private tuition (£50). Exhibitions: Morton, Queen's College, Belfast (£70); Franks, Coatham School, Redcar (£50); Le Sueur, University College, Aberystwith (£33⅓). Sizarships: Cummings, Henderson, Dale, Legg.

SCIENTIFIC SERIALS.

We have received a new instalment of the current volume of the Annals of the Moscow Observatory (series ii. vol. i. fasc. 2), published in French and German by Prof. Bredichin. It contains four papers, by the editor, on the comets of 1886 and 1887 I.; the results of M. Bélopolsky's observations of the last total solar eclipse at Yurievets, with interesting reproductions of photographs of the corona, and remarks upon the movements on the surface of the sun; photoheliographic observations made in 1885, by the same author; photometric observations, by W. Ceraski; and a paper on the rotation of the red spot in Jupiter, by P. Sternberg. All published observations which were made in Europe and the States from 1879 to February 1888 are given, and the conclusion is, that the spot did not change its position in 1879 and 1880, but has changed it by 0·0893h. since 1880–81, which change cannot be explained by mere variations of its shape.

The last volume of the *Mémoires* of the Kharkoff Society of Naturalists contains a very full list of vascular plants in the neighbourhood of Voronezh, by L. Gruner. The names of 778 species are given, but, the aquatic plants being still only imperfectly known, the Voronezh flora will probably include more than 800 species of Phanerogams.—The *Mastigophoræ* and *Rhizopodæ* of the salt lakes of Slavyansk are described by M. Vysotski; the *Chlorosporæ* of Kharkoff, by M. Alexéenko; and the *Chrysididæ* and *Tenthredinidæ* of Kharkoff, by Prof. Jarochewsky.

Journal of the Russian Chemical and Physical Society, vol. xx. fasc. 7.—Full reports on the eclipse of the sun of August 19, 1887 (continued). The reports of the various observations at Krasnoyarsk are given in full.—Notes on the action of acids, the tertiary acetate of amyl, and on the combinations of amylene with acids, by D. Konovaloff.

SOCIETIES AND ACADEMIES.

London.

Royal Society, December 6.—"On *Thylacopardus australis*, Owen. By Sir Richard Owen, F.R.S.

This paper, illustrated by drawings of the natural size, was descriptive of a skull discovered in one of several small caverns at a depth of 80 feet from the surface, in New South Wales. The essential characters of the dentition were those of the feline mammals, save that the piercing and killing teeth were the foremost pair of incisors; the work of molars was mainly done by a single large trenchant or sectorial tooth on each side of both jaws. This tooth was followed by a small tubercular molar in close contact therewith, and by a second similar molar with an intervening vacancy. The latter character is that by which the present fossil differs from the Australian one described in the author's work "The Extinct Mammals of Australia," 2 vols. quarto, 1877. The largest carnivorous kind, equalling the lion in size, bears the name of *Thylacoleo*; the skull of the present fossil shows that a Carnivore of the size of a leopard formerly, also, roamed over the land of kangaroos. These, being the largest native quadrupeds seen by Banks and Captain Cook, were described by Dr. Shaw under the name of *Macropus major*.

Anthropological Institute, December 11.—Francis Galton, F.R.S., President, in the chair.—Dr. J. G. Garson exhibited a new form of anthropometric instrument, specially designed for the use of travellers.—Dr. R. H. Codrington read a paper on social regulations in Melanesia. The part of Melanesia in view comprised the Northern New Hebrides, the Banks's Islands, Sta. Cruz, and the South-Eastern Solomon Islands. The social regulations which obtain among the people were described from personal observation, and from information given by natives. A considerable portion of the whole subject was thus in view, and with particular differences there is a general agreement, from which a wider likeness throughout the Melanesian population may be inferred. The social regulations dealt with were only those relating (I.) to *Marriage*, and (II.) to *Property*. *I. Social Regulations relating to Marriage.* (1) The entire arrangement of society depends on the division of the whole people, in every settlement, large or small, into two or more classes, which are exogamous, and in which descent follows the mother. This division comes first of all things in native thought, and all social arrangements are founded upon it. A woman regards mankind as divided into husbands and brothers; a man regards womankind as divided into wives and sisters—at least, on about the same level of descent. (2) The members of these divisions are all intermixed in habitation, property, subordination to a chief, and in the well-understood relationship through the father; the divisions, therefore, are not tribes. (3) Examples from two regions—(*a*) where these divisions are two, as in the Banks's Islands and Northern New Hebrides; (*b*) where there are more than two, as in Florida, in the Solomon Islands. (*a*) 1. Where there are two divisions there is no name to either. In Mota there are two *veve* (distinction); in Lepers' Island two *wai-vung* (bunch of fruit). 2. The divisions are strictly exogamous; irregular intercourse between members of the same is a heinous crime; avoidance of the person and name of father-in-law, &c., is the custom. 3. No communal marriage in practice, or tradition of it; yet a latent consciousness of the meaning of the words used for husband and wife, mother, &c. The story of Qat shows individual marriage. The levirate, and practice of giving a wife to set up a nephew in the world. 4. Descent through the mother makes the close relation of sister's son and mother's brother; the son takes his mother's place in the family pedigree. Certain rights of the sister's son with his uncle. The mother is in no sense head of the family. The bridegroom takes his bride into his father's house, if not into his own. 5. A certain practice of *couvade* prevails. 6. No capture in marriage. Adoption of no importance. (*b*) 1. In Florida, in the Solomon Islands, and the neighbourhood, is found an example of four or six divisions, called *kema*. In strict exogamy, descent following the mother, and local and political intermixture, all is the same as in the Banks's Islands. But each *kema* has its name, and each has its *buto*, that which the members of it must abstain from. The names are some local, some taken from living creatures. The *buto* is mostly something that must not be eaten. 2. Question whether totems are present. The bird which gives its name to one *kema* is not the *buto* of it, can be eaten. Comparison from the Island of Ulawa. 4. Exceptional condition of part of Malanta and San Cristoval, in the apparent absence of exogamous divisions of the people, and in descent being counted through the father. *II. Property and Succession. A.* 1. Land is everywhere divided into (1) the town; (2) the gardens; (3) the bush. Of these, the first two are held in property, the third is unappropriated. 2. Land is not held in common, *i.e.* each individual knows his own; yet it is rather possession and use for the time being of what belongs to the family, and not to the individual. A chief has no more property in the land than any other man. Sale of land was very rare before Europeans came; and sale of land by a chief beyond his own piece, no true sale. Example at Saa of the fixed native right of property in land. Abundance makes land of little value. 3. Land reclaimed from the bush by an individual, and the site of a town founded on the garden ground of an individual, has a character of its own. 4. Fruit-trees planted by one man on another's land remain the property of the planter and his heirs. In a true sale the accurate and particular knowledge of property in land and trees is remarkably shown. 5. Personal property is in money, pigs, canoes, ornaments, &c. *B.* 1. The regular succession to property is that by which it passes to the sister's son, or to others who are of kin through the mother. 2. But that which a man has acquired for himself he may leave to his sons, or his sons and their heirs may claim. This is the source of many quarrels, the character of a piece of land being forgotten, or disputed by the father's kin. 3. Hence a tendency to succession to the father's property by his sons follows on the assertion of paternity, and the occupation of new ground. 4. A man's kin still hold a claim on his personal property, but his sons, who are not his kin, will generally obtain it.—In the absence of the author, Dr. Edward B. Tylor read a paper by Mr. A. W. Howitt on Australian message sticks and messengers. The use of message sticks is not universal in Australian tribes, and the degree of perfection reached in conveying informarion by them differs much. Some tribes, such as the Dieri, do not use the message stick at all, but make use of emblematical tokens, such as the net carried

by the *pinya*, an armed party detailed by the council of headmen of the tribe to execute its sentences upon offenders. Other tribes, such as the Kurnai, use pieces of wood without any markings. Others, again, especially in Eastern Queensland, use message sticks extensively, which are often elaborately marked, highly ornamented, and even brightly painted. No messenger, who was known to be such, was ever injured. The message stick was made by the sender, and was kept by the recipient of the message as a reminder of what he had to do. For friendly meetings the messenger of Kurnai, of Gippsland, carried a man's kilt and a woman's apron hung on a reed; but for meetings to settle quarrels or grievances by a set fight, or for hostile purposes generally, the kilt was hung upon the point of a spear. Among the Wotjoballŭk of the Wimmera River in Victoria, the principal man among them prepares a message stick by making certain notches upon it with a knife. The man who is to be charged with the message looks on, and thus learns the connection between the marks upon the stick and his message. A notch is made at one end to indicate the sender, and probably notches also for those who join him in sending the message. If all the people of a tribe are invited to attend a meeting, the stick is notched from end to end; if part only are invited, then a portion only of the stick is notched; and if very few people are invited to meet or referred to in the verbal message, then a notch is made for each individual as he is named to the messenger. The messenger carried the stick in a net-bag, and on arriving at the camp to which he was sent, he handed it to the headman at some place apart from the others, saying to him, "So-and-so sends you this," and he then gives his message, referring, as he does so, to the marks on the message stick. The author gives an explanation of the method adopted for indicating numbers, which fully disposes of the idea that the paucity of numerals in the languages of the Australian tribes arises from any inability to conceive of more numbers than two, three, or four. A messenger of death painted his face with pipe-clay when he set out, but did not in this tribe carry any emblematical token. Among the Wirajuri of New South Wales, when the message was one calling the people together for initiation ceremonies, the messenger carried a "bull-roarer," a man's belt, a man's kilt, a bead string, and a white head band, in addition to the message stick. In New South Wales, the Kaiabara tribe use message sticks cut in the form of a boomerang, to one end of which a shell is tied. As a rule the notches on a message stick are only reminders to the messenger of the message he is instructed to deliver, and are unintelligible to a man to whom they have not been explained; but certain notches appear to have a definite meaning and to indicate different classes; and among the Adjadura there is an approach to a fixed rule, according to which these sticks are marked, so that they would convey a certain amount of meaning definitely to an Adjadura headman independently of any verbal message.

Mathematical Society, December 13.—J. J. Walker, F.R.S., President, in the chair.—Dr. Glaisher, F.R.S., communicated a geometrical note by Mr. H. M. Taylor.—Mr. Love read a paper on the equilibrium of a thin elastic spherical bowl.—The President (Prof. Greenhill, F.R.S., in the chair) contributed some illustrations of a former paper on a method in the analysis of ternary forms.—The Secretary read an abstract of a paper on a method of transformation with the aid of congruences of a particular type, by Mr. J. Brill.

—

EDINBURGH.

Royal Society, December 3.—Sir Douglas Maclagan, Vice-President, in the chair.—The Chairman gave an opening address.—Dr. John Murray communicated a paper by Mr. H. B. Brady on the Ostracoda collected in the South Sea Islands. One fresh-water specimen obtained in New Zealand is described. The rest were collected between the tide-marks or at depths of not more than 6 fathoms. The internal structure is not described, as the specimens were preserved in the dry state. Fifty new species and two new genera occur.—Dr. Murray communicated also a paper by Dr. O. von Linstow on *Pseudalius alatus*, Leuck., collected by Mr. Robert Gray in the Arctic Seas, and other species of the genus. A detailed description of this Entozoon is given, it having been only once previously described, and that imperfectly. Six other species of the same genus are described—Prof. Patrick Geddes read the first part (botanical and zoological) of a restatement of the theory of organic evolution. He drew attention to the two tendencies—vegetative and reproductive—which exist in organic nature, and asserted that evolution is the result of the universal subordination of the former to the latter.

STOCKHOLM.

Royal Academy of Sciences, December 12.—Contributions to our knowledge of the habits of solitary wasps, by Prof. Chr. Aurivillius.—On the singular points of such functions as are defined by non-linear differential equations, by Prof. Mittag-Leffler.—On the influence of the woods on the climate of Sweden, by Dr. Hamberg.—Singular generatrices in algebraic rule surfaces, by Prof. Björling.—On the systematic value of the varieties of herring, by Prof. F. A. Smitt.—On dinitronaphthalin-sulphon acid and some of its derivatives, by Herr P. Hellström.—On naphthoë acids, by Dr. Ekstrand.—On the action of fuming sulphuric acid on amido-naphthalin-sulphon acids, by Herr Forsling.—On the structure of the auricles in the Echinococonidæ, by Prof. S. Lovén.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Puff: Mrs. Macquoid (S.P.C.K.).—Rides and Studies in the Canary Islands: C. Edwardes (Unwin).—Elementos de Estatika Grafica: J. Schloske, traducidos del Alemán por V. Balbin (Buenos Aires).—Tratado de Geometria Analitica: J. Casey; traducido del Inglés por V. Balbin (Buenos Aires).—Carl von Linné's Ungdomsskrifter, 1, 2 (Stockholm).—*Challenger* Report—Zoology, vol. xxviii. (Eyre and Spottiswoode).—Elementary Building Construction and Drawing: E. J. Burrell (Longmans).—Atlas of Chemistry, part 1: V. V. Branford (Edinburgh, Livingstone).—Visitors' Guide to Salem (Salem, Mass.).—Bibliography of Astronomy for the Year 1887: W. C. Winlock (Washington).—The Beginning of American Science—The Third Century: G. Browne Goode (Washington).—On the Variation of Decomposition in the Iron Pyrites, 2 parts: A. A. Julien.—Journal of the Royal Microscopical Society, December (Williams and Norgate).—Essex Institute Historical Collections, vol. xxiv., January to December 1887 (Salem, Mass.).—Botanische Jahrbücher für Systematik Pflanzengeschichte, und Pflanzengeographie, Zehnter Band, iv. SCIENTIFIC WORTHIES.

XXV.—James Joseph Sylvester.

JAMES JOSEPH SYLVESTER, born in London on September 3, 1814, is the sixth and youngest son of the late Abraham Joseph Sylvester, formerly of Liverpool.[1] He was educated at two private schools in London, and at the Royal Institution, Liverpool, whence he proceeded in due course of time to St. John's College, Cambridge. In these early days he manifested considerable aptitude for mathematics, and so it was not matter for surprise that he came out in the Tripos Examination of 1837 as Second Wrangler; being incapacitated, by the fact of his Jewish origin, from *taking* his degree, he was not able to compete for either of the Smith's Prizes. In more enlighted times (1872) he had the degrees of B.A. and M.A., by accumulation, conferred upon him, and received therewith the honour of a Latin speech from the Public Orator. He himself says: "I am perhaps the only man in England who am a full (voting) Master of Arts for the three Universities of Dublin, Cambridge, and Oxford, having received that degree from these Universities in the order above given: from Dublin, by *ad eundem;* from Cambridge, *ob merita;* from Oxford, by decree." He is now D.C.L. of Oxford, LL.D. of Dublin and Edinburgh, and Hon. Fellow of St. John's College, Cambridge. It is still open for him to receive yet higher recognition from his own *alma mater.*

Prof. Sylvester became a student of the Inner Temple, July 29, 1846, and was called to the Bar on November 22, 1850.[2] He has been Professor of Natural Philosophy at University College, London; of Mathematics at the University of Virginia, U.S.A.;[3] then ten years later Professor at the Royal Military Academy, Woolwich; and again, after a five years' interval, Professor of Mathematics at the Johns Hopkins University, Baltimore, U.S.A., from its foundation in 1877. Finally, in December 1883, he was elected Savilian Professor of Geometry at Oxford, in succession to Prof. Henry Smith.[4] His first printed paper was on Fresnel's optical theory (in the *Phil. Mag.*, 1837).

We can here only briefly allude to a communication which was accompanied by many important results: we refer to the Friday evening address (January 23, 1874) to the Royal Institution, "On Recent Discoveries in Mechanical Conversion of Motion." He says:—"It would be difficult to quote any other discovery which opens out such vast and varied horizons as this of Peaucellier's,—in one direction, descending to the wants of the workshop, the simplification of the steam-engine, the revolutionizing of the mill-wright's trade, the amelioration of garden-pumps, and other domestic conveniences (the sun of science glorifies all it shines upon) and in the other, soaring to the sublimest heights of the most advanced doctrines of modern analysis, lending aid to, and throwing light from a totally unexpected quarter on the researches of such men as Abel, Riemann, Clebsch, Grassmann, and Cayley. Its head towers above the clouds, while its feet plunge into the bowels of the earth."

The only works that Prof. Sylvester has published, we believe, are: (1) "A Probationary Lecture on Geometry, delivered before the Gresham Committee and the Members of the Common Council of the City of London, December 4, 1854," a slight thing which had to be written and delivered at a few hours' notice; (2) "Laws of Verse," 1870; (3) several short poems, sonnets, and translations, which have appeared in our columns and elsewhere.

Our notice would be incomplete without some record of the honours that have been conferred upon Dr. Sylvester. He was elected a Fellow of the Royal Society on April 25, 1839; has received a Royal Medal (1860) and the Copley Medal (1880), this latter rarely awarded, we believe, to a pure mathematician. On this last occasion, Mr. Spottiswoode accompanied the presentation with the words, "His extensive and profound researches in pure mathematics, especially his contributions to the theory of invariants and covariants, to the theory of numbers and to modern geometry, may be regarded as fully establishing Mr. Sylvester's claim to the award." He is a Fellow of New College, Oxford; Foreign Associate of the United States National Academy of Sciences; Foreign Member of the Royal Academy of Sciences, Göttingen, of the Royal Academy of Sciences of Naples, and of the Academy of Sciences of Boston; Corresponding Member of the Institute of France, of the Imperial Academy of Science of St. Petersburg, of the Royal Academy of Science of Berlin, of the Lyncei of Rome, of the Istituto Lombardo, and of the Société Philomathique. He has been long connected with the editorial staff of the *Quarterly Journal of Mathematics* (under one or another of its titles), and was the first editor of, and is a considerable contributor to, the *American Journal of Mathematics;* and he was at one time Examiner in Mathematics and Natural Philosophy in the University of London. He was not an original member of the London Mathematical Society (founded January 16, 1865), but was elected a member on June 19, 1865, Vice-President on January 15, 1866, and succeeded Prof. De Morgan as the second President on November 8, 1866. The Society showed its recognition of his great services to them and to mathematical science generally by awarding him its De Morgan Gold Medal in November 1887. Wherever Dr. Sylvester goes, there is sure to be mathematical activity; and the latest proof of this is the formation, during the last term at Oxford, of a Mathematical Society, which promises, we hear without surprise, to do much for the advancement of mathematical science there.

The writings of Sylvester date from the year 1837; the number of them in the Royal Society Index up to the year 1863 is 112, in the next ten years 38, and in the forthcoming volume 81, making 231 for the years 1837 to 1883: the number of more recent papers is

[1] Foster's "Hand-book of Men at the Bar" [2] Foster, *l.c.*

[3] The late Prof. Key, of University College and School, was the first occupant of the Chair, founded by Mr. Jefferson, once President of the United States, in 1824.

[4] He commences his Oxford lecture (NATURE, vol. xxxiii. p. 222), of date December 12, 1885, with the words: "It is now two years and seven days since a message by the Atlantic cable containing the single word 'elected' reached me in Baltimore informing me that I had been appointed Savilian Professor of Geometry in Oxford, so that for three weeks I was in the unique position of filling the post and drawing the pay of Professor of Mathematics in each of two Universities."

also considerable. They relate chiefly to finite analysis, and cover by their subjects a large part of it: algebra, determinants, elimination, the theory of equations, partitions, tactic, the theory of forms, matrices, reciprocants, the Hamiltonian numbers, &c.; analytical and pure geometry occupy a less prominent position; and mechanics, optics, and astronomy are not absent. A leading feature is the power which is shown of originating a theory or of developing it from a small beginning; there is a breadth of treatment and determination to make the most of a subject, an appreciation of its capabilities, and real enjoyment of it. There is not unfrequently an adornment or enthusiasm of language which one admires, or is amused with: we have a motto from Milton, or Shakespeare; a memoir is a trilogy divided into three parts, each of which has its action complete within itself, but the same general cycle of ideas pervades all three, and weaves them into a sort of complex unity; the apology for an unsymmetrical solution is—symmetry, like the grace of an eastern robe, has not unfrequently to be purchased at the expense of some sacrifice of freedom and rapidity of action; and, he remarks, may not music be described as the mathematic of sense, mathematic as the music of the reason? the soul of each the same! &c. It is to be mentioned that there is always a generous and cordial recognition of the merit of others, his fellow-workers in the science.

It would be in the case of any first-rate mathematician—and certainly as much so in this as in any other case—extremely interesting to go carefully through the whole of a long list of memoirs, tracing out as well their connection with each other, and the several leading ideas on which they depend, as also their influence on the development of the theories to which they relate; but for doing this properly, or at all, space and time, and a great amount of labour, are required. Short of doing so, one can only notice particular theorems—and there are, in the case of Sylvester, many of these, "beautiful exceedingly," which, for their own sakes, one is tempted to refer to—or one can give titles, which, to those familiar with the memoirs themselves, will recall the rich stores of investigation and theory contained therein.

A considerable number of papers, including some of the earliest ones, relate to the question of the reality of the roots of a numerical equation: in the several connections thereof with Sturm's theorem, Newton's rule for the number of imaginary roots, and the theory of invariants. Sylvester obtained for the Sturmian functions, divested of square factors, or say for the reduced Sturmian functions, singularly elegant expressions in terms of the roots, viz. these were $f_2(x) = \Sigma(a - b)^2(x - c)(x - d) \ldots$, $f_3(x) = \Sigma(a - b)^2(a - c)^2(b - c)^2(x - d) \ldots$, &c.; but not only this: applying the Sturmian process of the greatest common measure (not to $f(x), f'(x)$, but instead) to two independent functions $f(x)$, $\phi(x)$, he obtained for the several resulting functions expressions involving products of differences between the roots of the one and the other equation, $f(x) = 0$, $\phi(x) = 0$; the question then arose, what is the meaning of these functions? The answer is given by his theory of *intercalations:* they are signaletic functions, indicating in what manner (when the real roots of the two equations are arranged in order of magnitude) the roots of the one equation are intercalated among those of the other. The investigations in regard to Newton's rule (not previously demonstrated) are very important and valuable: the principle of Sturm's demonstration is applied to this wholly different question: viz. x is made to vary continuously, and the consequent gain or loss of changes of sign is inquired into The third question is that of the determination of the character of the roots of a quintic equation by means of invariants. In connection with it we have the noteworthy idea of *facultative* points; viz, treating as the coordinates of a point in n-dimensional space those functions of the coefficients which serve as criteria for the reality of the roots, a point is facultative or non-facultative according as there is, or is not, corresponding thereto any equation with real coefficients: the determination of the characters of the roots depends (and, it would seem, depends only) on the bounding surface or surfaces of the facultative regions, and on a surface depending on the discriminant. Relating to these theories there are two elaborate memoirs, "On the Syzygetic Relations &c.," and "Algebraical Researches &c.," in the Philosophical Transactions for the years 1853 and 1864 respectively; but as regards Newton's rule later papers must also be consulted.

In the years 1851–54, we have various papers on homogeneous functions, the calculus of forms, &c. (*Camb. and Dub. Math. Journal*, vols. vi. to ix.), and the separate work "On Canonical Forms" (London, 1851). These contain crowds of ideas, embodied in the new words, *cogredient*, *contragredient*, *concomitant*, *covariant*, *contravariant*, *invariant*, *emanant*, *combinant*, *commutant*, *canonical form*, *plexus*, &c., ranging over and vastly extending the then so-called theories of linear transformations and hyperdeterminants. In particular, we have the introduction into the theory of the very important idea of *continuous* or *infinitesimal* variation: say that a function, which (whatever are the values of the parameters on which it depends) is invariant for an infinitesimal change of the parameters, is absolutely invariant.

There is, in 1844, in the *Philosophical Magazine*, a valuable paper, "Elementary Researches in the Analysis of Combinatorial Aggregation," and the titles of two other papers, 1865 and 1866, may be mentioned: "Astronomical Prolusions; commencing with the instantaneous proof of Lambert's and Euler's theorems, and modulating through the construction of the orbit of a heavenly body from two heliocentric distances, the subtended chord, and the periodic time, and the focal theory of Cartesian ovals, into a discussion of motion in a circle and its relation to planetary motion"; and the sequel thereto, "Note on the periodic changes of orbit under certain circumstances of a particle acted upon by a central force, and on vectorial coordinates, &c., together with a new theory of the analogues of the Cartesian ovals in space."

Many of the later papers are published in the *American Mathematical Journal*, founded, in 1878, under the auspices of the Johns Hopkins University, and for the first six volumes of which Sylvester was editor-in-chief. We have, in vol. i., a somewhat speculative paper entitled "An application of the new atomic theory to the graphical representation of the invariants and covariants of binary quantics," followed by appendices and notes relating to various special points of the theory; and in

the same and subsequent volumes various memoirs on binary and ternary quantics, including papers (by himself, with the aid of Franklin) containing tables of the numerical generating functions for binary quantics of the first ten orders, and for simultaneous binary quantics of the first four orders, &c. The memoir (vols. ii. and iii.) on "Ternary cubic-form equations" is connected with some early papers relating to the theory of numbers. We have in it the theory of residuation on a cubic curve, and the beautiful chain-rule of rational derivation; viz. from an arbitrary point 1 on the curve it is possible to derive the singly infinite series of points ($1, 2, 4, 5, \ldots 3p \pm 1$) such that the chord through any two points, m, n, again meets the curve in a point $m+n$, $m \sim n$ (whichever number is not divisible by 3) of the series; moreover, the coordinates of any point m are rational and integral functions of the degree m^2 of those of the point 1.

There is in vol. v. the memoir, "A Constructive Theory of Partitions arranged in three acts, an Interact in two parts, and an Exodion," and in vol. vi. we have "Lectures on the Principles of Universal Algebra" (referring to a course of lectures on multinomial quantity, in the year 1881). The memoir is incomplete, but the general theories of nullity and vacuity, and of the corpus formed by two independent matrices of the same order, are sketched out; and there are in the *Comptes rendus* of the French Academy later papers containing developments of various points of the theory,—the conception of "nivellators" may be referred to.

The last-mentioned paper in the *American Mathematical Journal* was published subsequently to Sylvester's return to England on his appointment as Savilian Professor of Mathematics at Oxford. In December 1886, he gave there a public lecture containing an outline of his new theory of reciprocants (reported in NATURE, January 7, 1887), and the lectures since delivered are published under the title, "Lectures on the Theory of Reciprocants" (reported by J. Hammond), same *Journal* vols. viii. to x.; thirty-three lectures actually delivered, entire or in abstract, in the course of three terms, to a class in the University, with a concluding so-called lecture 34, which is due to Hammond. The subject, as is well known, is that of the functions of a dependent variable, y, and its differential coefficients, $y', y'', \ldots$, in regard to x (or, rather, the functions of $y', y'', \ldots$), which remain unaltered by the interchange of the variables x and y: this is a less stringent condition than that imposed by Halphen ("Thèse," 1878) on his differential invariants, and the theory is accordingly a more extensive one. A passage may be quoted:—"One is surprised to reflect on the change which is come over Algebra in the last quarter of a century. It is now possible to enlarge to an almost unlimited extent on any branch of it. These thirty lectures, embracing only a fragment of the theory of reciprocants, might be compared to an unfinished epic in thirty cantos. Does it not seem as if Algebra had attained to the dignity of a fine art, in which the workman has a free hand to develop his conceptions, as in a musical theme or a subject for painting? Formerly, it consisted in detached theorems, but nowadays it has reached a point in which every properly-developed algebraical composition, like a skilful landscape, is expected to suggest the notion of an infinite distance lying beyond the limits of the canvas." And, indeed, the theory has already spread itself out far and wide, not only in these lectures by its founder, but in various papers by auditors of them, and others,—Elliott, Hammond, Leudesdorf, Rogers, Macmahon, Berry, Forsyth.

Sylvester's latest important investigations relate to the Hamiltonian numbers: there is a memoir, *Crelle*, t. c. (1887), and, by Sylvester and Hammond jointly, two memoirs in the Philosophical Transactions. The subject is that of the series of numbers 2, 3, 5, 11, 47, 923, calculated thus far by Sir W. R. Hamilton in his well-known Report to the British Association, on Jerrard's method. A formula for the independent calculation of any term of the series was obtained by Sylvester, but the remarkable law by means of a generating function was discovered by Hammond, viz. $E_0, E_1, E_2, \ldots$, being the series $3, 4, 6, \ldots$ of the foregoing numbers, each increased by unity; then these are calculated by the formula $(1-t)^{E_0} + t(1-t)^{E_1} + t^2(1-t)^{E_2} + \ldots = 1 - 2t$, equating the powers of t on the two sides respectively: observe the paradox, $t = \frac{1}{2}$, then the formula gives $0 =$ sum of a series of positive powers of $\frac{1}{2}$.

Enough has been said to call to mind some of Sylvester's achievements in mathematical science. Nothing further has been attempted in the foregoing very imperfect sketch.

A. CAYLEY.

THE CREMATION OF THE DEAD.

The Cremation of the Dead. By Hugo Erichsen, M.D. (Detroit: D. O. Haynes and Co., 1887.)

THIS book is an appeal to the general public on the propriety of introducing the practice of cremation, universally, into civilized communities; or, as the author puts it, "it is a plea for the burning of the dead." He considers, and we are inclined to think he is right, that the period of fanatic and fierce opposition to cremation has passed, and has made way for a calm consideration of the subject. In 1874, he tells us, a Persian gentleman then resident in one of the Eastern States of the free and great Republic of America, who wanted to have his wife cremated, was compelled by an ignorant mob to resort to interment; but now the feeling has changed.

In our own country the same sensible desire to discuss the question of cremation, fully and freely, is fairly established at the present time; and so greatly has prejudice disappeared, that now the act of cremation has been carried out over fifty times at the Woking Cemetery alone. As Sir Spencer Wells shows, in an introductory chapter which he has written for the work before us, the obstacle of law in England against cremation has been removed, and relatives may resort to the cremation of their dead without any unreasonable impediments.

In saying so much in favour of freedom in regard to cremation, we must, however, in this country confine the freedom to the voice of the living. The wishes of the dead, though they may have been delivered up to the last moment in favour of cremation, and may even have been ordered in the will of the deceased, have no legal weight with the survivors. The writer of this article was called, quite recently, to see a lady who had rather suddenly died,

to determine that life was actually extinct. She had been haunted with the most terrible fears that she might be buried alive, fears much intensified by the existence in her family of a tradition that one of her relatives had actually been subjected to this awful ordeal. She had directed in her will that she was to be cremated, but her legal adviser, who had himself drawn out the document, discovered that it had no force in regard to the direction of cremation, and two of the nearest relatives having a determined and conscientious objection to the process, the body had to be interred. In this instance every precaution was taken that the body was absolutely dead, and even decomposed, before it was laid in the earth, and to this extent the wishes of the deceased were fulfilled; but the fact that the law does not respond to the wishes of the dead is a point to be remembered by all who would be cremated. The same failure of law seems to be operative in Italy, for we all remember that the final request of the great Garibaldi as to the disposal of his body by fire remains to the present moment disregarded.

Dr. Erichsen must at once receive the credit of having written the best book that has issued from the press on the subject of cremation. It is short and yet full, concise and yet complete. There are eight chapters: the first, a history of cremation; the second, the evils of burial, and the sanitary aspects of incineration; the third, cremation in times of war; the fourth, the processes of modern cremation; the fifth, the medico-legal aspect of incineration, and the objections to cremation; the sixth, burial alive, cremation from an æsthetic and religious point of view; the seventh, the present state of the cremation question.

The introductory letter by Sir Spencer Wells, to which reference has already been made, is an excellent prelude to the chapters above recorded. Sir Spencer Wells has for many years been a staunch and consistent advocate of cremation, and has put it on record that, when the time comes—may it be long delayed!—his body is to be destroyed by fire. He writes, therefore, with authority, as one who has well considered the subject in all its details, and has learned the best and most forcible answers to the many objections that have from time to time been raised against cremation. He quotes the late Dr. Parkes's statement "that neither affection nor religion can be outraged by any manner of disposal of the dead which is done with proper solemnity and respect to the earthly dwelling-places of our friends. The question should be placed entirely on sanitary grounds. Burying in the earth appears certainly to be the most insanitary plan." On the religious side of the question, Wells also adds a strong sentence from the late Lord Shaftesbury, who remarked to him that, if cremation were wrong, "what has become of the blessed martyrs who were burned at the stake in ancient and modern persecutions?"

We turn naturally, as scientific readers, to the section of Dr. Erichsen's work which treats on the sanitary aspect of the subject. This is not, in our view, the strongest part. In it the author has collated the widely reported instances of the spread of epidemics on the opening of burial-places where persons who died of contagious diseases, similar to maladies which have broken out, have been interred. But here three fallacies are suggested. In the first place, it is impossible to accept all the illustrations as illustrations strictly in point and entirely trustworthy—or, for the matter of that, any of the evidence as absolutely trustworthy—seeing that other causes which might have been at work to produce the effects named are not duly eliminated. In the second place, if the instances cited may be accepted as *primâ facie* evidence, they accord imperfectly with other instances, not of exceptional, but of every-day life, in which cemeteries and graveyards holding the remains of those who have died of contagious maladies have been partly or largely opened without any manifestation of the dangers referred to; or in which persons have lived for long series of years in close proximity to graveyards and cemeteries receiving the dead from infectious diseases, and yet have not suffered from those diseases more than others in other localities. There is at the present moment a cemetery near London, from which at times, emanations of the worst kind proceed, indicating that the cemetery is overcharged with dead, and ought at once to be closed; but no epidemic has broken out from it as a centre of contagion. In the third place, the evidence collected by the author, if it were accepted as mainly trustworthy, is not quite *ad rem.* It would be correct in so far as old burial-grounds and old modes of burial are concerned, but it would have no bearing whatever on the earth-to-earth system of burial which our countryman, Mr. Seymour Haden, has done so much to introduce and to perfect.

Dr. Erichsen's answer to these objections would be: Why linger at all over the bodies of the dead? they feel not, neither do they know. "It is of no consequence to the dead whether they rot in earth and originate miasmata, or are transformed by fire into pure white ashes. They feel as little of the process of decay as they do of the flame: their eye is surrounded by the same darkness, whether down in the deep grave or in the glowing light of the crematory furnace. But it is of greatest consequence to us, the living; and the only way to protect ourselves from poisonous infection by our dead is to burn them."

In this one sentence lies, in a scientific sense, the gist of the whole question. If it were true and demonstrable that the only way by which the living can be preserved from the dead is to burn the dead, every true man of science would support the principle of cremation out and out, and the practice would become universal in a very short space of time. Moreover, as Science, like Nature herself, has no morbid sentiments, but goes straight to and for the truth, she would not tarry long in making herself heard. It is just because the voice of Science cannot be so absolute that it demurs or hesitates. Her scholars inquire amongst the living of the day to see if they afford an answer to the important question. They ask: Are the persons whose duty it is to be nearest to the dead immediately after death—the upholsterers and the servants of the cemeteries and graveyards—more liable than others to the infectious diseases from their special occupations? and the answer which comes back is certainly negative. They ask other and similar questions:—How many times has it been known that a medical man in conducting the autopsy of a person who has died of a contagious affection has contracted the disease? How many women of the death-chamber have contracted disease from the dead? These questions also

receive a negative answer; and as a matter of course the man of science is, therefore, unable to be dogmatic or to strain a necessity: he cannot clearly recognize, on a "not proven" verdict, the duty of wounding the extremely sensitive feelings of millions of his fellow-men, on a subject that is amongst the most tender of all that pertains to humanity.

Our idea is that in the current state of public opinion, and in the current state of scientific knowledge, it is best to let the public feeling towards cremation work its own way, and to let earth-to-earth burial also have its free course.

Cremation will come partly by necessity, partly by a gradual sentiment in its favour. To force it by conjuring up dangers which do not exist is the very means of arresting it in its progress. We do not say that the work we have had under review is open to too severe criticism on these grounds; on the contrary, it adduces such a number of sound arguments in support of its case, and, on the whole, shows such a just and good weight on its own side, that we commend it as an excellent treatise—we should not improperly say standard treatise—on cremation.

ASSAYING.

Practical Metallurgy and Assaying: a Text-book for the use of Teachers, Students, and Assayers. By Arthur H. Hiorns. Pp. 471, with 91 Illustrations, Appendix, and Index. (London: Macmillan and Co., 1888.)

ASSAYING was a term originally used to denote the estimation, by the agency of heat, of a particular metal in an ore, alloy, or other metallic compound. Since the publication of Agricola's work in 1556, numerous English translations of foreign treatises on the subject have been published. Amongst these may be mentioned the translations of the works of Erker (1629), Barba (1674), and Cramer (1774). Assaying by the dry way has changed so little that the methods and instruments described in these old books might still be successfully used. Since the introduction, however, of the rapid and accurate wet processes, improvements have quickly followed each other, and from a particular ore a larger yield is now obtained than was formerly the case, so that the dry methods are, with a few exceptions, rapidly falling into disuse, as in many cases they do not indicate with sufficient precision the amount of metal actually present in the ore. The modern English literature of assaying is confined to Mitchell's large treatise, and to the chapters given in Percy's works and in Phillips's "Elements of Metallurgy." No small text-book, in which full cognizance is taken of wet processes, has hitherto been published, and a gap in our metallurgical literature has now been well filled by Mr. Hiorns's useful book, which is based on the course of instruction organized at the Royal School of Mines by Prof. W. C. Roberts-Austen, to whom the author, as an old pupil, dedicates his work. In all the Continental Schools of Mines, the instruction is conducted in a most unsatisfactory manner. Large classes rapidly pass through the various assaying processes, all the students working together with military precision at the Professor's word of command. In London, on the other hand, each student works independently, and is not permitted to pass from one metal to another until he can prove that he is able to constantly produce trustworthy results. As a student of the Royal School of Mines, Mr. Hiorns has thus had an excellent training for the task he has undertaken. Besides this, as Principal of the School of Metallurgy at the Birmingham and Midland Institute, he has had ample opportunity of ascertaining the wants of the average student.

Like so many of the text-books of science now published, Mr. Hiorns's book has been arranged to meet the requirements of the Science and Art Department Syllabus. The first part contains a number of experiments for the student to perform in order to elucidate the principles upon which metallurgy is based; the second part contains an account of the methods of assaying by dry methods; whilst the third deals with assaying by wet methods, and includes volumetric analysis and the analysis of furnace gases. The course is very systematically arranged, and it is certain that any student who has performed the experiments enumerated would be thoroughly well grounded in practical metallurgy. And the fact that such a book is now required by a large number of students in evening classes shows what excellent service the Science and Art Department is doing for practical metallurgy throughout the country.

The author discusses several of the newer methods, such as Turner's method of estimating carbon in iron, and alludes to recent researches, such as those of Beringer on the accuracy of the volumetric estimation of copper. He appears, however, to be unacquainted with the newer methods in use on the Continent, and it is to be regretted that he has not consulted the standard works of Balling and of Bruno Kerl, or the careful abstracts of foreign papers published in the Journals of the Chemical Society and of the Iron and Steel Institute. It is to be regretted, too, that there is a want of uniformity in the weights and measures adopted. Grains and grammes, ounces and cubic centimetres, are used indiscriminately. For industrial purposes, it was perhaps necessary that the "grains" should be retained. But, with regard to the "ounces," many assayers, who are familiar with metric measures, have no idea how many ounces make a pint. In the nomenclature and notation, there is also an unfortunate want of uniformity, as is shown by the indiscriminate use of the terms, oil of vitriol and sulphuric acid, carbonate of soda and sodium carbonate, hæmatite and hematite, OH_2 and H_2O, SO_4H_2 and H_2SO_4. The book is remarkably free from typographical errors. The name Fresenius is, however, spelt wrong in places (pp. 174, 183) and "oxide of silica" (p. 312) is a compound unknown to the chemist.

On the whole, the work is an excellent one, and will, no doubt, prove of great service to the teachers and students of classes in practical metallurgy. Chemists generally, accustomed to ordinary laboratory manipulation, will be interested to see how many operations there are, which, while differing from those with which they deal, are capable of affording very trustworthy results. The illustrations are of a very effective character, and are well executed from drawings that have been prepared with an amount of care not usual in figures of this class. Mr. Hiorns's literary style is far from faultless, but his instructions are always perfectly clear, and, to use the words of an old metallurgist, "he writes like one who hath black'd his Fingers and sing'd his Beard in metallick Operations."

B. H. B.

THE ORCHIDS OF THE CAPE PENINSULA.

The Orchids of the Cape Peninsula. By Harry Bolus, F.L.S. With Thirty-six Plates, partly coloured. Off-print from the Transactions of the South African Philosophical Society, 1888, Vol. V., Part 1. (Cape Town, 1888.)

"THIS," as the author informs us, "is an attempt to describe the Orchids growing on the peninsula of the Cape of Good Hope; to give their names and synonyms; to arrange them as far as possible in groups; to adduce the stations where they have been found, and their further distribution so far as known. To this is added a list of collectors; and of books and papers already published upon the subject of South African Orchidology." Mr. Bolus's name as an authority on Cape Orchids is already well known through his papers in the Journal of the Linnean Society; and the thoroughness with which his work has been done is vouched for by the fact that it has occupied a great part of his leisure time for several years, and embodies the results of a comparison of the Orchids of Thunberg's Herbarium, by Mr. N. E. Brown, A.L.S.; also by the fact that Lindley's Type Herbarium, and the General Herbarium, at Kew, where Mr. Bolus has been staying for several months, have been fully consulted.

The Cape peninsula is a tract of land about forty miles long, varying in width from about three to eleven miles, and has a total area of 197½ square miles; and it is interesting to note that in an area about one-fourth larger than the Isle of Wight, no less than 102 species, belonging to ten genera are found, thirty-three of which, so far as at present known, are endemic. The order is considered to take a position the fourth in importance in the flora (after Compositæ, Leguminosæ, and Ericaceæ), and to constitute 5·8 of the whole. The altitudinal range of the species is very interesting. The greater part of the area in question is occupied by a central mountain range, of which Table Mountain, which attains an elevation of 3562 feet, is the highest part. From Mr. Bolus's tables, it appears that fifty-nine species never descend into the plains to a lower elevation than 500 feet, twenty others are always found below this elevation, while the twenty-three remaining ones are indifferent in this respect. He also remarks that fifteen species have a vertical range of from 2000 to 3000 feet, and six species a range of more than 3000 feet. This large vertical range, which is shared in common with many of the flowering plants, Mr. Bolus attributes to the equability of the temperature, and of the moisture of the atmosphere at different elevations, owing to the close proximity of the sea on nearly every side.

One of the species is of such great beauty that there has been some danger of its ultimate extinction; on which points the following will be read with interest. "The peerless *Disa uniflora* is in its glory on the rivulets of Table Mountain in February. . . . This beautiful flower is the object of universal admiration, and the name which has been given to it, the 'Pride of Table Mountain,' indicates the honour in which it is held. It is, indeed, the queen of terrestrial Orchids in the southern hemisphere, as *Cypripedium spectabile* may be said to reign, though with less magnificence, in the northern. . . . It is still abundant on Table Mountain, although of late years large quantities of the tubers have been annually exported to Europe, and much needless destruction, arising from wasteful gathering by unskilled hands, resulted. But the summit of the mountains being Crown land, the Government has recently intervened, and restricted the removal of tubers within reasonable limits, so that, if this supervision be continued, there will be little reason to fear the extinction of this truly noble species."

The thirty-six, partly coloured, plates, which represent the rarer or least-known species, are drawn by the author, and the dissections and botanical details are admirably portrayed; though in some cases the outline only is given, and a little shading would have enhanced their effect.

Respecting the structure and homologies of Orchideæ, largely cited from Darwin, and with a plan of the flower from the same source, it may be pointed out that the so-called union of the two lateral stamens of the outer staminal whorl with the median petal, to form the lip, was disputed, and, I think, satisfactorily disproved, by Crueger; a view which has been since confirmed by Dr. Masters, in the case of *Cypripedium*. The papers in question appear to have been overlooked, but the oversight detracts little from the value of this admirably executed work. To those who wish to procure copies, the omission of the publisher's name is unfortunate. Messrs. West, Newman, and Co., of Hatton Garden, E.C., are the printers, and may be able to supply the work.

R. A. ROLFE.

OUR BOOK SHELF.

Carl von Linné's ungdomsskrifter. Samlade af Ewald Ährling, och efter hans död med statsunderstöd utgifvna, af K. Vetenskaps-Akademien. Första serien, första häftet. (Stockholm: P. A. Norstedt & Söner, 1888.)

THIS is the first part of the youthful writings of Linnæus, collected by the late Dr. Ewald Ährling, and published, under a State grant, by the Royal Swedish Academy of Science. The work as a whole is to be divided into two series of several parts each, the first series including a record of the life of Linnæus up to the year 1734, with botanical addenda. The second will contain the author's account of his journeys in Lapland (1732), hitherto printed only in English; in Dalabergslagen (1733); in Dalecarlia (1734); and notes on his sojourn abroad (1735). In the first series are the following purely botanical works:—"Hortus Uplandicus," after Tournefort's system, from the original in the possession of the Linnean Society; "Hortus Uplandicus," after Tournefort's system, with an addendum, and a new division of Umbellatæ (1730), from the original in the Leufsta Library; "Hortus Uplandicus," after the author's method the sexual system (1731), original in possession of the Rev. J. Johansson, at Ifvetofta; and "Adonis Uplandicus," after the sexual system (1731), original in the Leufsta Library.

The majority of readers will find that the most interesting of the papers in the part before us is the great botanist's diary. The original of this, wholly in the handwriting of Linnæus, is one of the two autographs in the possession of the Linnean Society. It contains thirteen closely-written pages, and we must conclude, from a remark in the diary, that it was written between 1730 and 1735. To judge from difference of writing and ink, additions were made at a later date.

The diary is followed by "Catalogus Plantarum

Rariorum Scaniæ item Catalogus Plantarum Rariorum Smolandiæ" (1728), in the possession of the De Geer family (Leufsta Library); and by "Spolia Botanica" (1729), the original of which is in the possession of the Linnean Society, and is considered to have been finished towards the end of 1729. This seems, however, improbable, the date of dedication (to Prof. Roberg, one of Linnæus's teachers at Upsala) being May 5, 1729. The work is accompanied by twelve facsimile drawings of the principal representatives of the Lapland flora.

This part of the first series contains copious and explanatory notes by the late Dr. Ährling, a work which must have entailed very great labour. After his death, his editorial duties were undertaken by Dr. M. B. Swederus. The second series will be edited by Prof. G. Lindström.

First Principles of Physiography. By John Douglas. (London: Chapman and Hall, 1889.)

THE ever-increasing number of text-books on this subject is evidence that the study of physiography is gaining in popularity. The object of the book before us, as the author states in his "Prologue on the Beach," is to give a systematic statement of the nature of the forces at work in the world, and of the changes which the matter of the world undergoes. The book is obviously designed to cover the syllabus issued by the authorities at South Kensington, although no mention of this fact is made.

The first part of the book deals with force, but for some reason or other, force is not defined until p. 26, and there only in an obscure place. The author's notion of treating elementary chemical ideas is somewhat peculiar; to make statements about positive and negative elements without explaining the meanings of those terms, and to use formulæ like NH_3 and H_2SO_4 (p. 36) without naming the compounds they represent, is scarcely the way to inspire a student with confidence in his teacher.

No less than 23 pages are devoted to tables, all of more or less interest to students of physiography.

Perhaps the chief novelty of the book is the introduction of copious quotations from, and references to, standard works. Their introduction as footnotes, however, is rather objectionable, as it tends to discontinuity. A good deal of information is undoubtedly given, but the style is not such as to commend it to those who are just commencing the study of science, and these, it must be remembered, constitute the majority of those who take up the subject of physiography.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

"Engineers" *versus* "Professors and College Men."

PROF. GREENHILL is, himself, one of many proofs that the distinction between "Engineers" and "Professors and College Men" is a Cross Division. Every "Engineer" ought to be a "highly-trained College man." If he were, he would know at once, from the very first sentence of the Principia (*Quantitas materiæ est mensura ejusdem* &c., &c.) that mass is the personal property of a body, one of the invariable things in nature:—and not an accidental property dependent, for its amount and even for its very existence, on the momentary surroundings. The letter M has hitherto been used by Newtonians in this sense. If anyone has since attached to it another and different sense, *he* is responsible for the consequent confusion. Would it not be well if Prof. Greenhill, and the School to which he has attached himself, would kindly leave to Newtonians their M, as defined for them by their Master; and (with severely logical consistency) turn it upside down (thus, W) when they wish to embody their own revolutionary definition? No Newtonian will refuse to recognize $Wv^2/2g$ as a correct expression for so much energy:—though he will probably think it both clumsy and complex, and will prefer to write as usual his $Mv^2/2$.

I am curious to know how Prof. Greenhill would deal with physical Astronomy. What is his measure of the earth's mass? According to the analogy of his "*units of* g *pounds*" the earth's mass is at present (near perihelion) to be spoken of as if it were some 6 or 7 per cent. greater than it was six months ago!

The whole of this attempt to improve on Newton is caused by unwillingness to face, once for all, the small amount of labour and thought requisite for learning or teaching how to pass from one system of units to another. A properly taught student learns, very early in his career, that this is no awful and mysterious process:—in fact that it is, throughout, quite as simple in principle as is the passing from miles per hour to feet per second.

And I venture to assert that such a student would attack with ease and confidence any *fair* question (*i.e.* one free from mere tricks or traps) connected with the subject. This one, for intance:—

"How many of the following quantities (taken in order) can, by selection of the requisite system of units, be simultaneously expressed by one and the same *number*. *First*, when that number is given? *second*, when it is not?

(*a*) The weight of a ton, at sea-level, at the equator.

(*b*) The speed of light *in vacuo*.

(*c*) The average kinetic energy of a particle of hydrogen at 0° C.

(*d*) The minimum compressibility of water at low pressures.

(*e*) The mean angular velocity of the earth about the sun.

Express the requisite units in C.G.S. measure, when the common numerical value, above mentioned, is $\log_e\pi$; and also when it is not assigned."

Of course it is understood, and this is my answer to Prof. Greenhill's first question, that *the student would be furnished with all the necessary data*, experimental or otherwise, expressed in definite *assigned* units.

In answer to Prof. Greenhill's second question I need only say that it is no part of my case to assert that all statements, made by "College men," are *necessarily* characterized by definiteness, by accuracy, or even by common-sense.

December 21, 1888. P. G. TAIT.

The Sun-spot Cycle.

IT may interest some of the readers of NATURE to learn that an expected change has just been observed upon the solar surface.

It is a well-established fact that in each new series of sun-spots the first spots of the cycle are seen in high solar latitudes, and that as the number of spots increases there is a common drift towards the sun's equator, the spot area becoming most extensive as the sixteenth parallel of heliographic latitude is reached. During late years the spots have been diminishing in number and size, and approaching the solar equator; and in the past twelve months very few spots have been seen on the sun's surface, and all in low latitudes, that recorded on December 21 being 4° south of the solar equator. The close of the year has, however, witnessed a change, as a small spot is recorded on the Stonyhurst drawing of December 30 at 36° south latitude. Spots near the equator will probably continue to be observed for some time, but, whilst they are diminishing, those in higher latitudes will be on the increase. S. J. PERRY.

Stonyhurst Observatory, Lancashire, December 31, 1888.

"Renaissance of British Mineralogy."

MR. FLETCHER'S admirable address on a "Renaissance of British Mineralogy," of which a report was published in a recent issue of your paper, calls timely attention to the present condition of the science. Mineralogy as a popular study seems dead: the chemists have deserted it for a study of complex organic compounds, so that it has become a mere hanger-on of geology. The science is now not thoroughly taught in any institution in this country, and teachers therefore have no means of acquiring knowledge, in the only really useful way, by working under the acknowledged masters. This is especially the case with

crystallography, which must at present, unfortunately, be regarded as a branch of mineralogy. And if they cannot acquire sound knowledge, how can they teach well? I feel quite sure that if the Science and Art Department would institute a summer course for teachers, where they would not have to waste their time over the merest rudiments, but could study practically the methods of crystal measurements, and the higher branches of mineralogical research, it would be largely taken advantage of by teachers and those who intend to become teachers. Failing this, I for one should be glad to know of any institution in this country or in Germany where such instruction could be obtained during the summer months. A TEACHER.

Glasgow, December 31, 1888.

Ventilating Bees.

I DO not know whether it is generally known that here, and I believe in other tropical countries, there are in every hive what one can only describe as "ventilating bees." I mean that during the hot season two or three bees post themselves, on their heads, at the entrance of the hive, and fan the interior with the incessant motion of their wings. They are relieved at intervals by fresh bees, who carry on the process. They are kept to their duty by a sort of patrol of bees to insure their incessant activity. This is a well-authenticated and known fact, and as such may interest your readers. EVA M. A. BEWSHER.

Mauritius, November 21.

Sonorous Sand at Botany Bay.

REFERRING to the correspondence with regard to the so-called "musical sands," which has appeared in your columns, it may be of interest to record the fact that sand with similar properties is found in Botany Bay, New South Wales, not far from the spot where Captain Cook first landed. When displaced by pressure from above, or disturbed with the hand or stick, this sand emits a musical sound, which appears to vary in intensity according to the degree of moisture which it contains. Should any of your correspondents wish for specimens, I shall be happy to forward a small quantity to them. A. SIDNEY OLLIFF.

Australian Museum, Sydney, November 16, 1888.

HOW RAIN IS FORMED.[1]

IN certain villages in the Indian Central Provinces, besides the village blacksmith, the village accountant, the village watchman, and the like, there is an official termed the *gápogári*, whose duty it is to make rain. So long as the seasons are good and the rain comes in due season, his office is no doubt a pleasant and lucrative one. It is not very laborious, and it is obviously the interest of all to keep him in good humour. But if, as sometimes happens, the hot dry weather of April and May is prolonged through June and July, and week after week the *ryot* sees his young sprouting crops withering beneath the pitiless hot winds, public feeling is wont to be roused against the peccant rain-maker, and he is led forth and periodically beaten until he mends his ways and brings down the much-needed showers.

You will hardly expect me, and I certainly cannot pretend, to impart to you the trade-secrets of the professional rain-maker. Like some other branches of occult knowledge which Madam Blavatsky assures us are indigenous to India, this art of rain-making is perhaps not to be acquired by those who have been trained in European ideas; but we can at least watch and interrogate Nature, and learn something of her method of achieving the same end; and if her scale of operations is too large for our successful imitation, we shall find that not only is there much in it that may well challenge our interest, but it may enable us to some extent to exercise prevision of its results.

Stated in the most general terms, Nature's process of rain-making is extremely simple. We have its analogue in the working of the common still. First, we have steam or water vapour produced by heating and evaporating the water in the boiler; then the transfer of this vapour to a cooler; and finally we have it condensed by cooling, and reconverted into water. Heat is communicated to the water to convert it into vapour, and when that heat is withdrawn from it, the vapour returns to its original liquid state. Nature performs exactly the same process.

In the still, the water is heated until it boils; but this is not essential, for evaporation may take place at all temperatures, even from ice. A common little piece of apparatus, often to be seen in the window of the philosophical instrument maker, and known as Wollaston's cryophorus, is a still that works without any fire. It consists of a large glass tube with a bulb at each end, one of which is partly filled with water: and, all the air having been driven out of the tube by boiling the water, it is hermetically sealed and allowed to cool. It then contains nothing but water and water vapour, the greater part of which re-condenses when it cools. Now, when thus cold, if the empty bulb be surrounded by ice, or, better, a mixture of ice and salt, the water slowly distils over, and is condensed in the colder bulb, and this without any heat being applied to that which originally contained the water. And this shows us that all that is necessary to distillation is that the condenser be kept cooler than the evaporater.

Nevertheless, at whatever temperature it evaporates, water requires heat, and a large quantity of heat, merely to convert it into vapour; and this is the case with the cryophorus; for if the evaporating bulb be wrapped round with flannel, and so protected from sources of heat around, the water cools down until it freezes. That is to say, it gives up its own heat to form vapour. A simple experiment that anyone may try with a common thermometer affords another illustration of the same fact. If a thermometer bulb be covered with a piece of muslin, and dipped into water that has been standing long enough to have the same temperature as the air, it gives the same reading in the water as in the air. But if when thus wetted it be lifted out and exposed to the air, it begins to sink at once, owing to the evaporation of the water from the wet surface, and it sinks the lower the faster it dries. In India, when a hot wind is blowing, the wet bulb sometimes sinks 40° below the temperature of the air.

Now this is a very important fact in connection with the formation of rain, because it is owing to the fact that water vapour has absorbed a large quantity of heat—which is not sensible as heat, but must be taken away from it before it can be condensed and return to the liquid state—that vapour can be transported as such by the winds for thousands of miles, to be condensed as rain at some distant part of the earth's surface.

I have said that the quantity of absorbed heat is very large. It varies with the temperature of the water that is evaporating, and is the greater the lower that temperature. From water that is on the point of freezing it is such that one grain of water absorbs in evaporating as much heat as would raise nearly 5½ grains from the freezing to the boiling point. This is called the latent heat of water vapour. As I have said, it is quite insensible. The vapour is no warmer than the water that produced it, and this enormous quantity of heat has been employed simply in pulling the molecules of water asunder and setting them free in the form of vapour, which is merely water in the state of gas. All liquids absorb latent heat when they evaporate, but no other known liquid requires so much as water.

Many things familiar in everyone's experience find their explanation in this absorption of latent heat. For instance, we feel colder with a wet skin than with a dry one, and wet clothes are a fruitful source of chills when the body is in repose; although, so long as it is in active exercise and producing a large amount of heat, since the evaporation

[1] A Lecture delivered by H. F. Blanford, F.R.S., at the Hythe School of Musketry on November 19.

only carries off the excess, no ill consequence may ensue. Again, if a kettle be filled with ice-cold water and put on a gas stove, suppose it takes ten minutes to bring it to boil. In that ten minutes the water has absorbed as much heat as raises it from 32° to 212°, an increase of 180°. Now, if it be left boiling, the gas-flame being kept up at the same intensity, we may assume that in every succeeding ten minutes the same quantity of heat is being absorbed by the water. But it gets no hotter: it gradually boils away. And it takes nearly an hour, or more than five times as long as it took to heat it, before the whole of the water has boiled away, since all this heat has been used up in converting it into steam. It was by an experiment of this kind that Dr. Black, in the last century, discovered the fact of latent heat, and determined its amount; and it was the knowledge of this fact that led James Watt to his first great improvement in the steam-engine.

One more example I may give, which those who have been in India will be able to appreciate, and which those who intend to go there may some day find useful to know. Nothing is more grateful in hot dry weather than a drink of cold water. Now, ice is not always to be had, but when a hot wind is blowing, nothing is easier than to get cold water, if you have a pot or bottle of unglazed earthenware, such as are to be had in every bazaar, or, what is better, a leather water-bottle, called a *chhàgal*, or a water-skin. All these allow the water to soak through and keep the outside wet; and if any one of them be filled with water and hung up in a hot wind, in the course of half an hour or an hour, the evaporation from the outside will have taken away so much heat that the contents may be cooled 20° or 30°, notwithstanding that the thermometer may stand at 110° or 115° in the shade. Soda-water may be cooled in the same way if wrapped in straw and kept well wetted while exposed to the wind. But it is of little use to do as I have seen natives do sometimes, viz. put the bottles into a tub of water in a closed room. It is the evaporation that carries off the heat, otherwise the water is no cooler than the air around.

Now to return to our subject. The atmosphere always contains some vapour which the winds have taken up from the ocean, lakes, rivers, and even from the land, for there are but few regions so dry and devoid of vegetation that there is no moisture to evaporate. The quantity of water thus evaporated from large water surfaces is a question of some importance to engineers, who have to take account of the loss from reservoirs and irrigation tanks, and a good deal of attention has been given to measure the amount lost by evaporation. In England it has been found to vary in different years from 17 to 27 inches in the year, or say from $1\frac{1}{2}$ to $2\frac{1}{4}$ inches per month on an average. Now, since in the east of England the rainfall is only about 24 inches in the year, it follows that in that part of the Kingdom the loss by evaporation from a water surface is not very much less than the rain falling directly on the surface.

In dry countries the evaporation may exceed the local rainfall. In the tropics it has been found to average from $3\frac{1}{2}$ to 6 inches per month in the dry season. In the case of a large tank at Nagpur, constructed to supply the city with water, it was found that the loss by evaporation, in the hottest and driest weather, was two and a half times as great as the quantity supplied for consumption.

These statistics will give some idea of the enormous evaporation that goes on from the water surfaces of the globe, and to this must be added all that takes place from the land. In the case of light showers, nearly the whole of the rain is re-evaporated; and probably, on an average, half of the total rainfall on the land is thus lost sooner or later, leaving not more than half for the supply of springs and rivers.

The quantity of vapour in the air is very variable. To us, in England, the west and south-west winds are the dampest, coming direct from the Atlantic, and north-east winds are the driest. The cause of their extreme dryn es I shall endeavour to explain presently. It is no doub partly due to the fact that they reach us from the land surface of Europe, but partly also to another cause to which I shall have to advert later on.

The quantity of vapour in the air is usually ascertained by the hygrometer, the ordinary form of which is a pair of thermometers, one having the bulb wet, the other dry, and observing the depression of the wet bulb. The principle of this I have already explained. But the same thing may be ascertained more directly by passing a measured quantity of air through a light apparatus containing sulphuric acid, or some other substance that absorbs water vapour greedily, and weighing the whole before and afterwards. The increase of the second weighment gives the weight of water absorbed. By such means it has been ascertained that air at 60° can contain as much as $5\frac{3}{4}$ grains of vapour in each cubic foot, and that air at 80° can contain rather less than 11 grains in the same space. The quantity that air can hold increases therefore very rapidly with the temperature. But it is seldom that it contains this maximum amount, especially at the higher temperatures.

In order to condense any part of this vapour we must take away its latent heat. It is not sufficient merely to cool it till it reaches the temperature of condensation, but we have further to abstract $5\frac{1}{2}$ times as much heat as would raise the condensed water from the freezing to the boiling point. Before, however, proceeding to consider how this cooling is effected, the question arises, What is the condensing point? For, obviously, since water can evaporate at all temperatures, so we should expect that it may condense at all temperatures. On what, then, does the condensing point depend?

I mentioned just now that air at the temperature of 60° can contain as much as $5\frac{3}{4}$ grains of vapour, and at 80° rather less than 11 grains in each cubic foot. Obviously, then, if air at 80°, containing this maximum quantity, be cooled to 60°, it must get rid of more than 5 grains, or nearly half its vapour, and this excess must be condensed. I speak of air containing these quantities, but in point of fact it makes no appreciable difference whether air be present or not. An exhausted glass vessel of one cubic foot capacity can hold $5\frac{3}{4}$ grains of vapour at 60° and no more, and nearly 11 grains at 80° and no more; and if, when thus charged at 80°, its contents be cooled to 60°, more than 5 grains will be condensed. If, however, it contain only $5\frac{3}{4}$ grains at 80°, none will condense until the temperature falls to 60°, but any further cooling produces some condensation. Thus, then, the condensing point depends on the quantity of vapour present in the air, and is the temperature at which this quantity is the maximum possible for that temperature.

This preliminary point being explained, we may now proceed to inquire what means Nature employs to condense the vapour in the air, producing at one time dew and hoar-frost, at another time fog and cloud, and at another rain, hail, and snow.

Let us take the case of dew and hoar-frost first, as they are comparatively simple. And in connection therewith I may relate a little incident that took place at Calcutta some years ago. A gentleman, who had not much acquaintance with physical science, was sitting one evening with a glass of iced brandy and water before him. It was in the rainy season, when the air, though warm, is very damp, and he had a large lump of ice in his tumbler. On taking it up, he noticed to his surprise that the glass was wet on the outside, and was standing in quite a little pool of water on the table. At first he thought his tumbler was cracked, but putting his finger to his tongue he found the fluid tasteless. "Very odd!" he remarked; "the water comes through the glass but the brandy doesn't."

Now, however with our present knowledge we may be inclined to smile at the simplicity of this remark, it so

happens that up to the end of the last century very much the same explanation was popularly held to account for dew. It was supposed to be a kind of perspiration emitted from the earth, and no satisfactory explanation of the phenomenon had been arrived at by the physical philosophers of the day. It remained for Dr. Wells to prove, by a long series of observations and experiments, which have been quoted by Sir John Herschel and Mr. John Stewart Mill as a typical instance of philosophical inquiry, that the cold surface of grass and shrubs condenses the vapour previously held in suspension in the air, these surfaces being cooler than the air, and below its point of condensation. And such, of course, is also the case of the glass tumbler containing ice. Anyone may try the experiment for himself. To produce hoar-frost, it is only necessary to cool the condensing surface below the freezing point, which may be done by crushing some ice and mixing it with salt. A tin pot is better than a glass to make this experiment.

When not only the ground, but also the air to a considerable height above it, is cooled in like manner, we have the production of fog, fog being the form in which the vapour is first condensed, and consisting of water in drops too minute to be separately visible. The formation of fog is very much aided if the air be laden with smoke. Smoke consists of extremely minute particles of unburnt coal or other fuel, and these cool faster than the air at night, and so cool the air in contact with them. Each one of them, too, condenses water on its surface, and being thus weighted they sink and form that dense fog that Londoners know so well.

Clouds are essentially the same as fog, but formed high up in the air. But in their case, and that of rain, snow, and hail, another and different cooling agency comes into play, and this will require some preliminary explanation.

I dare say that some of you may at some time or other have charged an air-gun. And if so, you will be aware that when so charged the reservoir becomes pretty warm. Now this heat is produced, not, as might be supposed, by the friction of the piston in charging, but is due to the fact that work has been done upon the air by compressing it into a very small space; in other words, work has been converted into heat. If the compressed air be allowed to escape at once, its heat is re-converted into work. It has to make room for itself by thrusting aside the atmosphere into which it escapes, and when thus expanded it is no warmer than before it was compressed. Indeed, not so warm, for it will already have parted with some of its heat to the metal chamber which contained it. And if when compressed it is allowed to cool down to the ordinary temperature, and then to escape, it will be cooled below that temperature just as much as it was heated by compression. Thus, if in being compressed it had been heated 100°, say from 60° to 160°, and then allowed to cool to 60°, on escaping it will be cooled 100° below 60°, or to 40° below zero, which is the temperature at which mercury freezes. This is the principle of the cold air chambers now so extensively employed on ship-board for the transport of frozen provisions from New Zealand and Australia.

Bearing in mind, then, this fact—that air in expanding and driving aside the air into which it expands is always cooled—let us see how this applies to the case before us, the production of cloud and rain.

The volume of a given weight of air—in other words, the space it occupies—depends on the pressure to which it is subject: the less this pressure the greater its volume. If we suppose the atmosphere divided into a number of layers superimposed on each other, the bottom layer is clearly subject to the pressure of all those that rest on it. This is equal to about $14\frac{3}{4}$ pounds on every square inch of surface. Another layer, say 1000 feet above the ground, will clearly be under a less pressure, since 1000 feet of air are below it; and this 1000 feet of air weighs slightly less than half a pound for every square inch of horizontal surface. At 2000 feet the pressure will be less by nearly one pound per square inch, and so on. If, then, any mass of air begins to ascend through the atmosphere, it will be continually subject to less and less pressure as it ascends; and therefore, as we have already seen, it expands, and becomes cooler by expansion. Cooling from this cause is termed dynamic cooling. Its rate may be accurately computed from the work it has to do in expanding.

It amounts to 1° for every 183 feet of ascent if the air be dry or free from vapour, and if, as is always the case, it contains some vapour, the height will not be very much greater so long as there is no condensation. But so soon as this point is passed, and the vapour begins to condense as cloud, the latent heat set free retards the cooling, and the height through which this cloud-laden air must ascend to cool 1° is considerably greater, and varies with the temperature and pressure. When the barometer stands at 30 inches, and at the temperature of freezing, the air must rise 277 feet to lose 1°, and if the temperature is 60° nearly 400 feet.

Conversely, dry air descending through the atmosphere and becoming denser as it descends, since it is continually becoming subject to an increased pressure, is heated 1° for every 183 feet of descent; and fog and cloud-laden air at 30 inches of pressure and the freezing point will be warmed 1° in 277 feet only, or if at 60° nearly 400 feet of descent, owing to the re-evaporation of the fog or cloud and the absorption of latent heat.

Now let us see how these facts explain the formation of cloud; and first I will take the case of the common cumulus or heap-cloud, which is the commonest cloud of the day-time in fine weather.

When after sunrise the air begins to be warmed, the lowest stratum of the atmosphere, which rests immediately on the ground, is warmed more rapidly than the higher strata. This is because the greater part of the sun's heat passes freely through a clear atmosphere without warming it, and is absorbed by the ground, which gives it out again to the air immediately in contact with it. So soon as the vertical decrease of temperature exceeds 1° in 183 feet, the warm air below begins to ascend, and the cooler air above to descend, and this interchange gradually extends higher and higher, the ascending air being gradually cooled by expansion, and ceasing to rise when it has fallen to the same temperature as the air around it. This ascending air is more highly charged with vapour than that which descends to replace it, since, as was mentioned before, most land surfaces furnish a large amount of moisture, which evaporates when they are heated by the sun. This process goes on until some portion of the ascending air has become cooled to the point of condensation. No sooner does it attain this, than a small tuft of cumulus cloud appears on the top of the ascending current, and the movement which was invisible before now becomes visible. In a calm atmosphere each tuft of cloud has a flat base, which marks the height at which condensation begins, but it is really only the top of an ascending column of air. No sooner is this cloud formed than the ascent becomes more rapid, because the cooling which checked its further ascent now takes place at a much slower rate, and therefore the cloud grows rapidly.

On a summer afternoon when the air is warm and very damp, such cumulus cloud ascends sometimes to very great heights, and develops into a thunder-cloud, condensing into rain. Rain differs from fog and cloud only in the size of the water drops. In fog and cloud these are so minute that they remain suspended in the air. But as the cloud becomes denser, a number of them coalesce to form a rain-drop, which is large enough to overcome the friction of the air. It then begins to fall, and having to traverse an enormous thickness of cloud below, it grows larger and larger by taking up more and more of the

cloud corpuscules, so that when finally it falls below the cloud it may have a considerable size.

Such, then, is the mode in which rain is formed in an ordinary summer shower; and the more prolonged rainfall of stormy wet weather is the result of a similar process, viz. the ascent and dynamic cooling of the moist atmosphere. But in this case the movement is on a far larger scale, being shared by the whole mass of the atmosphere, it may be, over hundreds or thousands of square miles; and to understand this movement we shall have to travel somewhat further afield, and to inquire into the general circulation of the great atmospheric currents set in movement by the sun's action in the tropics, and modified by the earth's diurnal rotation and the distribution of the continents and oceans on its surface.

Before, however, entering on this subject, which will require some preliminary explanation, and in which we shall have to take account both of ascending and descending currents on a large scale, I will draw your attention to another and simpler case, in which both these classes of movements are prominently illustrated, and in which they exhibit their characteristic features in a very striking manner.

In the valleys of the Alps, more especially those to the north of the central chain, in Switzerland and the Tyrol, there blows from time to time a strong warm dry wind, known as the Föhn. It blows down the valleys from the central chain, melting the snows on its northern face, and although there is more or less clear sky overhead, all the southern slopes of the mountains are thickly clouded, and heavy rain falls on the lower spurs and the adjacent plain, replaced by snow at the higher levels up to the passes and the crest of the range. Cloudy weather also prevails to the north in Germany, and the weather is stormy over some part of Western Europe.

It is only since the general introduction of telegraphic weather reports and the construction of daily weather charts have enabled us to take a general survey of the simultaneous movements of the atmosphere over the greater portion of Europe, that this Föhn wind has been satisfactorily explained.[1] It is found that when a Föhn wind blows on the north of the Alps, the barometer is low somewhere to the north or north-west, in Germany, Northern France, or the British Isles, and high to the south-east, in the direction of Greece and the Eastern Mediterranean. Under these circumstances, since the winds always blow from a place of high barometer to one of low barometer, a strong southerly wind blows across the Alps. On their southern face it is forced to ascend, and therefore, as just explained, it is cooled and gives rain in Lombardy and Venetia, and snow at higher elevations. But having reached the crest of the mountains, it descends to the northern valleys, and being by this time deprived of a large part of its vapour, it becomes warmed in its descent, owing to compression. absorbs and re-evaporates the cloud carried with it, and is then further warmed at the rate of 1° for every 183 feet of descent. Thus it reaches the lower levels as a warm dry wind, its warmth being the effect of dynamic heating.

Other mountain chains afford examples of the same phenomenon. A very striking instance, which much impressed me at the time, is one that I witnessed many years ago in the mountains of Ceylon; and it was afterwards mentioned to me by Sir Samuel Baker, who had been equally struck by it. My own experience is as follows:—In June 1861, I paid a week's visit to the hill sanitarium of Newara Eliya, at an elevation of 6200 feet, on the western face of Pedro Talle Galle, the highest mountain in the island. The south-west monsoon was blowing steadily on this face of the range; and during the whole time of my stay it rained, as far as I am aware, without an hour's intermission, and a dense canopy of cloud enveloped the hill face, and never lifted more than a few hundred feet above the little valley in which Newara Eliya is built. But on leaving the station by the eastern road that leads across the crest of the range to Badulla, at a distance of five miles one reaches the *col* or dip in the ridge near Hackgalle, and thence the road descends some 2000 feet to a lower table-land which stretches away many miles to the east. No sooner is this point passed than all rain ceases and cloud disappears, and one looks down on the rolling grassy hills bathed in the sunshine of a tropical sun, and swept by the dry westerly wind that descends from the mountain ridge. In little more than a mile one passes from day-long and week-long cloud and rain to constant sunshine and a cloudless sky.

As an almost invariable rule, or at least one with few exceptions, ascending air currents are those that form cloud and rain, and descending currents are dry and bring fine weather. And this holds good whatever may be the immediate cause of these movements. We may now proceed to consider these greater examples to which I have already referred.

In the great workshop of Nature, in so far at least as concerns our earth, with but few exceptions, all movement and all change, even the movements and energies of living things, proceed either directly or indirectly from the action of the sun. Nowhere is this action more direct and more strikingly manifested than in the movements of the atmosphere. Were the sun extinguished, and to become, as perhaps it may become long ages hence, a solid cold sphere, such as Byron imagined, "wandering darkling in eternal space," a few days would suffice to convert our mobile and ever-varying atmosphere into a stagnant pall, devoid of vapour, resting quiescent on a lifeless earth, held bound in a more than Arctic frost. From such a consummation, despite the supposed decaying energy of our sun, we may, however, entertain a reasonable hope that we are yet far distant.

Bearing in mind the all-embracing importance of the sun, let us see how the great movements of the atmosphere are determined by the way in which the earth presents its surface to the solar rays.

Since the quantity of solar heat received on each part of the earth's surface depends on the directness or obliquity of his rays—in other words, on the height to which the sun ascends in the heavens at noon—being greatest where he is directly overhead, as in summer in the tropics, it follows that the hottest zone of the earth is that in the immediate neighbourhood of the equator, and the coldest those around the poles.

Did time allow, and were the necessary appliances at hand, it would be easy to show you that both as a matter of experiment, and also as a deduction from physical laws, there must be under such circumstances a flow of air from the colder to the warmer region in the lower atmosphere, and a return current above. And to a certain extent we have these constant winds prevailing for about 30° on either side of the equator, in the trade-winds, which blow towards the equator in the lower atmosphere, and the anti-trades blowing in the opposite direction at a great height above the earth's surface.

In the neighbourhood of the equator there is a zone extending right round the earth in which the barometer is lower than either to the north or the south. It is due to the greater heat of the sun, and it is towards this that the trade winds blow. It shifts to some extent with the seasons, being more northerly in the summer of the northern hemisphere, and more southerly in that of the southern hemisphere; and its average position is rather to the north of the equator, owing to the fact that there is more land in the northern than in the southern hemisphere, and that land is more heated by the sun than the ocean.

This simple wind system of the trades and anti-trades does not extend right round the earth, nor beyond 30° or

[1] The explanation was originally given by Prof. J. Hann, of Vienna.

40° of latitude in either hemisphere. Were the earth's surface uniformly land or uniformly water, there probably would be a system of trade-winds all round the globe, blowing from both hemispheres towards the equator; but even in that case they would not extend much, if at all, beyond their present limits. In the first place, every great mass of land sets up an independent system of air currents, since the land is hotter than the ocean in the summer, and colder in the winter. In the summer, therefore, there is a tendency to an indraught of air from the sea to the land in the lower atmosphere, and an outflow above, and in the winter the opposite; and this tendency modifies or interrupts the system of the trades and anti-trades. We have this tendency shown most distinctly in the monsoons of South-Eastern Asia, where, both in the India and China seas, a south-west wind in the summer takes the place which in the absence of the Asiatic continent would be held by a north-east trade-wind. And it is only in the winter that a north-east wind blows, and this is then termed the north-east monsoon.

In the second place, as I have said, the system of trade-winds could not in any case extend far beyond their present limits in latitude, owing to the fact that the earth is a sphere and not a cylinder. Let us fix our attention for a moment on the anti-trades—the upper winds which blow from the equator towards the poles. The equator, from which they start, is a circle about 24,900 miles in circumference; the poles are mere points, and, therefore, the whole of the air that blows towards the poles must turn back in any case before it reaches the pole, and must begin to turn back before it has gone very far on its journey. And, as a fact, a great part of it does turn back between 30° and 40° of latitude, which I have already mentioned as being the limit of the trade-winds. A part of the remainder descends to the earth's surface, and sweeps the Northern Atlantic and the North Pacific as a south-west wind.

On the chart which represents the average distribution of atmospheric pressure in January, there are two somewhat interrupted zones of high pressure over the ocean in these latitudes. These mark the regions in which the anti-trades descend to the earth's surface, and from which the trade-winds start. Over the ocean in all higher latitudes, both in the northern and southern hemispheres, the barometer is low—for the most part, indeed, much lower than over the equator; and the region intervening between the zones of high pressure and the seat of lowest pressure is that of predominant south-west, or at all events westerly, winds. Since our islands are situated on the border of this region of low pressure, south-west are our prevailing winds.

But now two questions arise: first, Why are these winds westerly, and not simply south winds? and second, How is it that the barometer is so low over the North Atlantic and North Pacific Oceans, and also in the southern hemisphere in high latitudes, seeing that in these latitudes, at least in winter, the sun's heat is so much less than at the tropics? The chart represents the state of things in midwinter of the northern hemisphere, and yet everywhere to the north of latitude 40° the deep blue tint indicates that the pressure is lower than even in the southern tropic, where the sun shines vertically overhead. Clearly this low pressure must be due to some other cause than the warmth of the air.

The explanation of this remarkable distribution of the atmospheric pressure, of the existence of two zones of high pressure in latitudes 30° to 40°, and of very low pressure in higher latitudes, except in so far as they are modified by the alternations of land and water, was first given by the American physicist, Prof. Ferrel. Its full demonstration is to be obtained only from the consideration of somewhat recondite mechanical laws, but a general idea of the causes operating may be gathered from very simple considerations, which may be demonstrated with a terrestrial globe.

Starting with the well known fact that the earth revolves on its axis once in the twenty-four hours, let us see what will be the consequence, if we suppose a mass of any ponderable matter—that is, any substance having weight, no matter whether light or heavy—to be suddenly transferred from the equator to latitude 60°.

As the circumference of the earth at the equator is about 24,900 miles, any body whatever, apparently at rest at the equator, is carried round the earth's axis at the rate of 1036 miles an hour. But in latitude 60°, where the distance from the axis is only half as great as at the equator, it is carried round at only half the same rate, or 518 miles an hour; and at the pole it simply turns round on its own axis. Supposing, then, a mass of air to be suddenly transferred from the equator to latitude 60°, with the eastward movement that it had at the equator, it would be moving twice as fast to the east as that part of the earth, and, to any person standing on the earth, would be blowing from the west with a force far exceeding that of a hurricane. It would be moving eastwards 518 miles an hour faster than the earth. Indeed, its movement would really be far greater than this. In virtue of a mechanical principle known as the law of the conservation of areas, which means that any body revolving round a central point, under the influence of a force that pulls it towards that point, describes equal areas in equal times, instead of only 518 miles, it would be revolving round the earth's axis 1554 miles an hour faster than that part of the earth. I need not, however, specially insist on this point, because, as a matter of fact, the air which constitutes the anti-trades is not suddenly transferred, but takes a day or two to perform its journey, and in the meantime by far the greater part of its eastward movement is lost by friction against the trade-wind which blows in the opposite direction underneath it. The point on which we have to fix our attention is that, when the anti-trades descend to earth, they still retain some of this eastward movement, and blow, not as south, but as south-west or west-south-west winds.

On the other hand, the trade-wind, which blows towards the equator, is coming from a latitude where the eastward movement is less than at the equator, and its own movement eastward is therefore less than that of the surface over which it blows. A person, therefore, standing on the earth, is carried eastward faster than the air is moving, and the wind seems to blow against him from the north-east. Similarly, to the south of the equator, the trade-wind, instead of blowing from the south, comes from the south-east.

Thus, then, we have in both hemispheres a system of westerly winds in all higher latitudes than 40°, and a system of easterly winds—viz. the trade-winds—between about 30° and the equator; and if the globe were either all land or all water, these systems would prevail right round the earth.

Now, it is the pressure of these winds, under the influence of centrifugal force, that causes the two zones of high barometer in latitudes 30° to 40°, and the very low pressure in higher latitudes. It is not difficult to understand how this comes about. You are probably aware that the earth is not an exact sphere, but what is termed an oblate spheroid—that is, it is slightly flattened at the poles and protuberant at the equator, the difference of the equatorial and polar diameters being about 26 miles. It has acquired this form in virtue of its rotation on its axis. If you whirl a stone in a sling, the stone has a tendency to fly off at a tangent, and, so long as it is retained in the sling, that tendency is resisted by the tension of the cord. In the same way, every object resting on

the earth, and the substance of the earth itself, has a tendency to fly off at a tangent, in consequence of its rotation on its axis, and this tendency is resisted and overcome by gravity. Were the earth not revolving, its form, under the influence of gravity alone, would be a true sphere. If it were to revolve more rapidly than at present, it would be still more oblate, flatter at the poles, and more bulging in the tropical zone; if less rapidly, the flattening and bulging would be less.

This is precisely what happens with the west and east winds of which we have spoken. West winds are revolving faster than the earth, and tend to make the atmosphere more protuberant at the equator than the solid earth; hence they press towards the equator, to the right of their path in the northern hemisphere, and this tendency increases rapidly in high latitudes. Easterly winds, on the other hand, tend to render the form of the atmosphere more nearly spherical, and they, too, press to the right of their path in the northern hemisphere or towards the pole. In the southern hemisphere, for the same reason, both press to the left. The result of these two pressures in opposite directions is to produce the two zones of high barometer in the latitudes in which we find them—viz. between the easterly trade-winds and the westerly winds, which are the anti-trades that have descended to the earth's surface. And the low barometer of higher latitudes is produced in like manner by the westerly winds pressing away from those regions.

Thus, then, we find that all this system of winds, and the resulting distribution of atmospheric pressure as indicated by the barometer, is the result of the sun's action in equatorial regions. It is this that gives the motive power to the whole system, so far as we have as yet traced it, and it is this that produces those great inequalities of atmospheric pressure that I have so far described.

It remains now to see how storms are generated by these westerly winds. In so far as they retain any southing, they are still moving towards the pole in the northern hemisphere—that is to say, they are advancing from all sides towards a mere point. Some portion of them must therefore be continually turning back as the circles of latitude become smaller and smaller. But they are now surface-winds, and in order so to return they must rise and flow back as an upper current. This they do by forming great eddies, or air-whirls, in the centre of which the barometer is very low, and over which the air ascends, and these great air-whirls are the storms of the temperate zone and of our latitudes. It is the ascent and dynamic cooling of the air in these great eddies that cause the prolonged rainfall of wet stormy weather. How the eddies originate, or, rather, what particular circumstance causes them to originate in one place rather than another, we can scarcely say, any more than we can say how each eddy originates in a rapidly-flowing deep river. Some very small inequality of pressure probably starts them, but, when once formed, they often last for many days, and travel some thousands of miles over the earth's surface.

Two such storms are represented on the charts of February 1 and 2, 1883, one on the coast of Labrador, the other to the south-west of the British Isles. The first of these appears on the chart of January 28, in the North Pacific, off the coast of British Columbia. On the 29th it had crossed the Rocky Mountains, and was traversing the western part of the Hudson's Bay Territory. On the 30th it had moved to the south-east, and lay just to the west of the Great Lakes, and on the 31st between Lake Superior and Hudson's Bay. On February 1 it had reached the position on the coast of Labrador shown in the chart, and on the 2nd had moved further to north-east, and lay across Davis's Straits, and over the west coast of Greenland. After this it again changed its course to south-east, and on February 4 passed to the north of Scotland, towards Denmark, and eventually on to Russia.

The second storm had originated off the east coast of the United States between January 28 and 29, and on the following days crossed the Atlantic on a course somewhat to north of east, till, on February 2, it lay over England.

These storms always move in some easterly direction, generally between east and north-east, and often several follow in rapid succession on nearly the same track. It is this knowledge that renders it possible for the Meteorological Office to issue the daily forecasts that we see in the newspapers. Were it possible to obtain telegraphic reports from a few stations out in the North Atlantic, these storm warnings could be issued with much more certainty, and perhaps longer before the arrival of the storm than at present. In the case of such storms as that which reached our islands on February 2, we often have such warnings from America, but their tracks are often more to the north-east, in the direction of Iceland, in which case they are not felt on our coasts, and hence the frequent failure of these American warnings.

It is the region of low pressure in the North Atlantic that is the especial field of these storms. As they pass across it, they produce considerable modifications in the distribution of pressure, but some of its main features remain outstanding. Thus there is always a belt of high barometer between the storm region and the trade-winds, and in the winter there is almost always a region of high barometer over North America, and another over Europe and Asia, however much they may shift their places, and be temporarily encroached on by the great storm eddies.

These regions of high pressure are the places where the winds descend, and, as I mentioned in the earlier part of this lecture, these winds are dry, and generally accompany fine weather. On the contrary, the eddies, where the air ascends, are damp and stormy, and especially that part of the eddy that is fed by the south-west winds that have swept the Atlantic since their descent, and so have become charged with vapour.

And now we are prepared to understand why east, and especially north-east winds are generally so dry. They are air that has descended in the area of high barometer that, especially in the winter and spring, lies over Europe and Asia, and has subsequently swept the cold land-surface, which does not furnish much vapour, and therefore they reach us as dry cold winds. To begin with, the air comes from a considerable height in the atmosphere, and in ascending to that height in some other part of the world, it must have got rid of most of its vapour in the way that has been already explained. In descending to the earth's level it must, of course, have been dynamically heated by the compression it has undergone, but all or nearly all this heat has been got rid of by radiation into free space on the cold plains and under the clear frosty skies of Northern Asia and Northern Europe, and it then blows outwards from this region of high barometer over the land, towards the warmer region of low barometer on the North Atlantic Ocean.

Thus we see that, in all cases, rain is produced by the cooling of the air, and that in nearly all, if not all, this cooling is produced by the expansion of the air in ascending from lower to higher levels in the atmosphere, by what is termed dynamic cooling. This last fact is not set forth so emphatically as it should be in some popular text-books on the subject, but it is an undoubted fact. It was originally suggested by Espy some forty years ago, but the truth is only now generally recognized, and it is one of the results which we owe to the great advance in physical science effected by Joule's discovery of the definite relation of equivalence between heat and mechanical work.

THE SOARING OF BIRDS.[1]

So much for sails. Now I want to make some suggestions, or suggest some queries, as to the *skimming* flight of birds, in reference to which a good deal of fresh observation has been possible during the voyage.

You perhaps recollect that when the British Association was at Glasgow, you asked me to put into writing, briefly, as a paper for your Section, some remarks on this subject which I had made to you in conversation, but that, owing to my hasty departure to attend the trial of H.M.S. *Shah*, I omitted to do this.

I had better briefly recite the above particulars here in order to make more clear the bearing of the new observations we (I and Tower) have made.

The view was that when a bird skims or soars on quiescent wings, without descending and without loss of speed, the action must depend on the circumstance that the bird had fallen in with, or selected a region where the air was ascending with a sufficient speed. In still air the bird, if at a sufficient height, could continue to travel with a steady speed, using his extended wings as a sort of descending inclined plane, the propelling force depending on the angle of the plane and on the equivalent of "slip,"—that is to say, on the excess of the angle of actual descent compared with the angle of the inclined plane. The steady speed would be attained when the weight of the bird and the sines of the angle of the plane = the bird's *air resistance*, including skin friction of wings—in fact one might say = simply the skin friction of the whole area, for the bird's lines are fine enough to justify this statement, since there is no wave-making to be done, and indeed experiment shows that the statement is true for "fish-formed" bodies moving wholly and deeply immersed in water. Of course the bird's angle of actual descent is greater than that of the quasi-inclined plane, owing to the equivalent of "slip" in the wings. Under these simultaneously acting and correlated conditions there is of course—or probably—some total angle of descent which enables the bird to minimize his rate of approach to the earth in still air. If when there is a wind the configuration of the ground or any other circumstances can produce a local ascent of air more rapid than the bird's minimum rate of descent when soaring in still air, he may continue to soar indefinitely by keeping in the region where the air is thus ascending.

Now, in most cases where one sees birds "soaring," it is easy to see that they have plainly selected such a region, and for a long time I felt confident that the only two even apparent exceptions I had encountered were such as to *prove* not to *invalidate* the rule. One of these exceptions was that once, when the sea in Torbay was in a state of glassy calm, I noticed a large gull thus soaring at some distance from the shore,—watching it with a pair of binoculars, so that I was sure of the quiescence of the wings. But here the riddle was at once solved by the observation of what I had not at first noticed—the dark trace of the front line of a fresh sea-breeze advancing all across the bay. Such an advance with a definitely marked front, encountering an extended body of quiescent air, involved of course an ascent of air in the region of the encounter, and this was where the bird was soaring. The other exception was that when at sea I had often noticed birds thus soaring near the ship. The solution was that, so far as I had then noticed, the birds always selected a region to leeward of the ship, where the eddies created by the rush of air past her hull, &c., might readily have created local ascending currents.

The new exceptions we have seen since we have approached the Cape entirely set these two solutions at defiance.

[1] Extract from a letter of the late William Froude to Sir W. Thomson, of February 5, 1878, received after Mr. Froude's death. Reprinted from the Proceedings of the Royal Society of Edinburgh, March 19, 1888.

The first exception we noticed was in the flight of some albatrosses. We were sailing, and steaming (at low speed, being short of coal), nearly due east in the latitude of the Cape, with the wind light and variable abaft the beam, and with a well-marked south-west swell of about 8 to 9 seconds period, and varying from 3 or 4 feet to 8 or 9 feet from hollow to crest. The speed of such waves would be from 24 to 27 knots.

Under these conditions the birds *seemed* to soar almost *ad libitum* both in direction and in speed; now starting aloft with scarcely, if any, apparent loss of speed; now skimming along close to the water, with the tip of one or other wing almost touching the surface for long distances, indeed now and then actually touching it. The birds were so large that the action could be clearly noted by the naked eye even at considerable distances; but we also watched them telescopically, and assured ourselves of the correctness of our observations. The action was the more remarkable owing to the lightness of the wind, which sometimes barely moved our sails, as we travelled only 5 knots before it, by help of the screw.

After long consideration the only explanation of at all a rational kind which presented itself was the following, which indeed presents the action of a *vera causa*, and one which was very often certainly in accordance with the birds' visible movements, though it was often also impossible either to assert or to deny the accordance; and anyhow the question arises, Is the *vera causa* sufficient? I will try to trace its measure

When a wave is say of 10 feet in height and say 10 seconds period (a case near enough to ours to form the basis of a quantitative illustration) the length of the wave from crest to crest is just 500 feet, the half of which space, or 250, the wave of course traverses in 5 seconds, and assuming the wave to be travelling in a calm, it must happen approximately that during the lapse of this 5 seconds the air which at the commencement of the interval lay in the lowest part of the trough has been lifted to the level of the crest, or must have risen 10 feet, so that its mean speed of ascent has been 2 feet per second (10 feet in 5 seconds). And since (as is well known) the maximum speed of an harmonic motion is $\frac{\pi}{2}$ times, or nearly $1\frac{1}{2}$ times its mean speed, it follows that along the side of the wave at its mid-height the air must approximately be ascending at the rate of 3 feet per second, and if the bird were so to steer its course and regulate its speed as to conserve this position he would have the advantage of a virtual upward air current having that speed.

NOTES.

The Berlin Academy of Sciences has presented 2000 marks (£100) to Prof. Leopold Auerbach (Breslau), and the same amount to Dr. Franz Schütt (Kiel), to aid them in their physiological researches. Dr. Freudenthal, Professor of Philosophy at Breslau, and Herr von Rebaur-Paschwitz, the astronomer, have received 1500 marks (£75) each.

At the last meeting of the Scientific Committee of the Royal Horticultural Society, Mr. Henslow called attention to the fact that the year 1889, besides being the centenary of the chrysanthemum in Europe, is that of the dahlia in England. It was introduced by the Marchioness of Bute in 1789, and figured with single and double forms in the *Botanical Magazine*, vol. xliv., t. 1885, and the *Botanical Register*, vol. i. t. 55.

The death of Mr. J. J. Coleman, F.R.S.E., is announced. He died at the age of fifty. For some time he was manager of the works of Young's Paraffin and Mineral Oil Company, Glasgow; and in this capacity he carried out some important experimental investigations for the utilization of so-called waste

products. Afterwards he invented the refrigerating machine which bears his name, a machine which has increased and cheapened the available supply of fresh meat.

On Tuesday, the 8th inst., the second of the series of one-man photographic exhibitions at the Camera Club will be open to visitors on presentation of card. The Exhibition will continue for about six weeks. The object of this series of Exhibitions is to bring together in turn representative collections of the work of the best photographic artists. By the co-operation of Mr. Harry Tolley, of Nottingham, the Camera Club is enabled to exhibit a representative set of his photographs. These pictures are large direct work, and are printed in the permanent platinum process.

A course of six lectures on "The Science of Brewing" will be given at the Finsbury Technical College by Dr. E. R. Moritz, commencing Wednesday, January 23, and being continued on successive Wednesday evenings. Other courses of special lectures will be given during the present term by Prof. Perry, on "The Differential Calculus and its Application to Problems of Electrical and Mechanical Engineering"; by Prof. S. P. Thompson, on "Optical Principles and Practice"; and a special laboratory course on "Electro-deposition" (plating and typing), by Mr. Rousseau.

According to the *Standard* of December 29, 1888, Hampshire was visited, at 11 o'clock on the morning of the 28th, with what was believed to be an earthquake. There were, it is reported, a severe subterranean rumbling and a concussion in the neighbourhood of Emsworth Common. A horse and cart passing at the time were visibly shaken, and two men were nearly knocked off their legs. There was a violent rustling of the trees in the neighbourhood, and the shock appeared to extend over a wide area.

On Sunday, December 23, a severe shock of earthquake was experienced in Calcutta and throughout Bengal. In Rajshahye large fissures opened, whence hot liquid mud was ejected. The Calcutta Correspondent of the *Times*, reporting these facts by telegraph on December 30, said no loss of life had been heard of.

Several severe shocks of earthquake were felt in Bosnia, on December 18, especially at Rogatica, Cajnica, Pleolje, and Poljancic.

The University of Edinburgh continues to attract a very large number of students. During the past year, according to the Edinburgh Correspondent of the *Times*, the total number of matriculated students was 3532, as against 3459 last year, 2667 in 1878, and 1564 in 1868. Of this total, 1008 were enrolled in the Faculty of Arts, 108 in the Faculty of Divinity, 474 in the Faculty of Law, and 1942 in the Faculty of Medicine. Of the students of medicine 832 (or 43 per cent.) belonged to Scotland, 705 (or fully 36 per cent.) were from England and Wales, 36 from Ireland, 79 from India, 247 (or nearly 13 per cent.) from British colonies, and 43 from foreign countries.

At the Bath meeting of the British Association, a Report was presented by the Committee which had been appointed to consider the advisability and possibility of establishing in other parts of the country observations upon the prevalence of earth tremors similar to those now being made in Durham. Considering that much is being done with the object of securing suitable forms of instruments, and that these investigations are still incomplete in many ways, the Committee felt that it would be premature for them to select and recommend any special recorder at present. They, however, emphasized the view that, whilst carefully finished, highly sensitive, and necessarily expensive seismoscopes, made to record with as much accuracy as possible the time, form, and intensity of each set of tremors, are very desirable, and indeed indispensable, yet only a comparatively small number of such instruments would be required in a general scheme of seismographical observatories. Such instruments, moreover, could only be used with effect in carefully selected situations, and otherwise under very special conditions. On the other hand, comparatively rough, cheap, and easily used instruments, which could do little more than afford fairly accurate time-records, would be required in large numbers, and must form a most important portion of such a scheme. The Committee hoped that at the next meeting of the Association they might be in a position to present a Report containing definite recommendations.

The Chief Signal Officer of the United States reports that in the reorganization of the Record Division of the Signal Office he found a large amount of valuable rainfall data, furnished by voluntary observers prior to 1874. With a view of making these records available, he has published them in an atlas of rain charts of the United States, for each month of the years 1870–74; these will be found especially useful in the study of weather conditions over that country. He also states that an examination of the records of the voluntary observers shows that it will be possible to further utilize them in the preparation of normal temperature charts, which he hopes to be able to issue with the Monthly Weather Review at an early date. An eighteen-year normal monthly rain-chart is now being regularly issued in this Review.

In December 1877, Prof. F. E. Nipher established a volunteer weather service in Missouri, the object being primarily to investigate the rainfall of that State, and he has now published the results in a paper entitled "Missouri Rainfall." It contains maps and tables showing the average monthly amounts for ten years ending 1887, at thirty-one stations, together with the maximum and minimum monthly and yearly falls. The yearly averages vary from 31·4 inches to 45·7 inches.

In a recent lecture on Bacteria, delivered at Brooklyn, Dr. George M. Sternberg pointed out that the rapid progress of bacteriology in Germany has been due, to a very considerable extent, to the enlightened policy of the Government. Dr. Sternberg is of opinion that if, during the past ten years, the Americans had had a well-equipped laboratory, under proper direction, the medical corps of the army and navy could easily have supplied men who would have done good work in this department of research. He thinks it is not creditable to the United States as a nation that Americans have contributed so little to the advance of bacteriology. "Let us hope, however," he added, "that we are entering upon a new era. Here in Brooklyn private munificence has provided the means of research which the National Government should have provided long since; and here, at least, the fault will rest with the profession, if active workers are not found to avail themselves of the facilities provided for making original researches in bacteriology, in physiology, and in experimental pathology." The "private munificence" referred to is that of Dr. Hoagland, who has equipped a laboratory at Brooklyn. This laboratory, which has been organized in accordance with the best models, is to be devoted exclusively to scientific research, and to instruction in physiology, pathology, histology, and bacteriology.

The tenth volume of the Proceedings of the United States National Museum has been issued. The series to which this volume belongs consists of papers prepared by the scientific corps of the National Museum; of papers by others, founded upon the collections in the National Museum; and of brief records of interesting facts from the correspondence of the Smithsonian Institution.

The new number—the sixth—of the *Internationales Archiv für Ethnographie* completes the first volume of this excellent

periodical. Among the plates is a coloured representation of the deerskin mantle, ornamented with shell work, recorded to have belonged to the Virginian Chief, Powhattan. Dr. E. B. Tylor contributes, in English, an account of this interesting object, which forms one of the treasures of the Ashmolean. It belongs to the Tradescant collection, which was the nucleus of the museum of Elias Ashmole. It seems that there were in use among the Powhattans three kinds of mantles, viz. of dressed skins embroidered with beads (including shells), of furs, and of feather work. In the original collection of Tradescant there were specimens of all three kinds. Of these, the shell-embroidered mantle alone remains. It measures about 2·2 m. in length by 1·6 m. in width. The two deerskins forming it are joined down the middle; no hair remains. The ornamental design consists of an upright human figure in the middle, divided by the seam; a pair of animals; thirty-two spirally formed rounds (two in the lowest line have lost their shells); and the remains of some work in the right lower corner. Dr. Tylor says that the decorative shell-work is of a kind well known in America. The shells used are *Marginella*: so far as Mr. Edgar A. Smith is able to identify them in their present weathered state, *M. nivosa*. Among the other contents of the number are some notes, in German, on the ethnography of Mexico, by Carl Breker, and an attempt, by M Messikommer, to describe some elements of what may have been the intellectual life of the inhabitants of ancient lake-dwellings.

In the new number of the Transactions of the Leicester Literary and Philosophical Society, there is a useful and interesting paper, by Mr. Montagu Browne, Curator of the Town Museum, Leicester, on "Evidences of the Antiquity of Man in Leicestershire." He begins with objects of bone and horn, then examines the remains of pottery, and finally deals with articles in bronze and stone. Palæolithic implements have not yet been discovered in Leicestershire, but Mr. Evans, in a passage quoted by Mr. Browne, is of opinion that they may be found there. "It is by no means impossible," writes Mr. Evans, "that you may succeed in finding them. It is a little far north, but I doubt whether the glaciers persisted so long in that part of England as they did in the Lake District, and in Wales."

Messrs. Cassell and Co. are issuing, in monthly parts, a popular edition of "The Story of the Heavens," by Sir Robert S. Ball, the Royal Astronomer of Ireland. The work, which is well printed on good paper, will be completed in eighteen parts. With Part I., which we have just received, a star map is given.

The "Educational Annual" for 1889, compiled by Edward Johnson, has been issued. Messrs. G. Philip and Son are the publishers. The work is designed to place within reach of the general public a concise summary of authentic information, drawn from official or other trustworthy sources, relative to primary and secondary education, in a form convenient for reference. Information relating to training colleges for teachers and teachers' associations has been included.

A book, entitled "Rides and Studies in the Canary Islands," by Mr. Charles Edwardes, has just been published (Fisher Unwin). The author quaintly explains that it is written "for the entertainment both of those who visit the Canary Islands and those who do not." A considerable part of the book has already appeared in the form of articles in magazines and journals. Those who have already read these fragments will not object to find them again among Mr Edwardes's lively and pleasant sketches.

We have received a diary called "The Perennial Diary," which a good many people may find useful. It is not intended to supersede ordinary diaries. Each page is devoted to a single day of the year, and events occurring on that day in different years may all be entered on the same page. The volume is issued by Mr. John Heywood, of Manchester and London.

The Free Libraries Committee of Manchester are able to give, in their thirty-sixth Annual Report, a most favourable account of all departments of the institutions under their charge. The number of the buildings in which the work of the Committee is carried on has been increased to ten by the establishment of the Hyde Road Reading Room, which was opened some time ago by the Mayor, in the presence of a large and enthusiastic meeting of the inhabitants of the district. In the course of the last twelve months the number of readers at the various libraries and reading-rooms (*i.e.* the number of visits they have made) reached an aggregate of nearly four millions and a half, or about a quarter of a million more than in the previous year. There has been an increase also in the number of books read. The number used for home reading and for perusal in the reading-rooms has been 1,606,874, against 1,462,028 volumes read in the preceding twelve months. The daily average of volumes used in all the Libraries was 4464.

In the letter on "Nose-blackening as preventive of Snow-blindness," by Mr. A. J. Duffield (vol. xxxviii. p. 172), *for* "New Zealand" *read* "New Ireland."

The additions to the Zoological Society's Gardens during the past week include a Common Kestrel (*Tinnunculus alaudarius*) captured at sea, presented by Mr. Thomas Austin; a Pyxis Tortoise (*Pyxis arachnoides*) from Durban, Natal, presented by Colonel J. H. Bowker, F.Z.S.; a Rat-tailed Snake (*Trigonocephalus lanceolatus*) from St. Lucia, W.I., presented by the West Indian (Natural History) Exploration Committee; two Concave-casqued Hornbills (*Buceros bicornis*) from India, deposited; a —— Squirrel (*Sciurus* sp. inc.) from Burmah, two Ceylonese Hanging Parrakeets (*Loriculus asiaticus*) from Ceylon, purchased.

OUR ASTRONOMICAL COLUMN.

Detection of New Nebulæ by Photography.—Prof. Pickering gives a brief account, in No. 6 of the Annals of Harvard College Observatory, vol. xviii., of some experiments he has recently conducted as to the advantages of a photographic doublet over an ordinary astronomical object-glass for astronomical work, and especially in photographing nebulæ. A number of plates were exposed upon the region of Orion, the instrument used being the Bache telescope, which has a photographic doublet with an aperture of 8 inches and a focal length of 44 inches; each plate covered a region 10° square, the definition being good within $3\frac{1}{2}°$ of the centre of the plate. The result of the experiments was the detection of twelve new nebulæ; fourteen nebulæ were seen on the photographs that were also given in Dreyer's Catalogue, and four nebulæ in the Catalogue were not represented on the plates. A similar proportion of discovery over the entire sky would mean some 4000 or 5000 new nebulæ, and 400 plates would be sufficient for a complete survey, provided here was no overlapping, and no plates proved defective.

Comets Faye and Barnard, October 30.—The following ephemeris for Faye's comet is in continuation of that given in Nature (vol. xxxix. p. 186). The ephemeris for Barnard's comet is by Herr Spitaler (*Astr. Nach.*, No. 2871). Both are for Berlin midnight:—

	Comet 1888 *d* (Faye).		Comet 1888 *f* (Barnard, Oct. 30).

NOTES ON METEORITES.[1]

VII.

Possible Connection between the Jets and Envelopes seen in Cometary Swarms.

THE jets observed in comets when near the sun are very various in form. The concentric envelopes seen at times are much more regular; an idea of their appearance will be gathered from the accompanying illustration of Donati's comet.

It has not yet been clearly ascertained whether the jets and envelopes are connected phenomena—that is, whether the jets are true whirls of the meteorites themselves—or whether they represent volatilization of the vapours of the nucleus in a particular direction, which vapours subsequently assume a concentric form. In Halley's comet, at all events, this was not

Fig. 21.—Concentric envelopes as illustrated by Donati's comet.

observed. Sir John Herschel writes concerning this: "The bright smoke of the jets, however, never seems to be able to get far out towards the sun, but always to be driven back and forced into the tail, as if by the action of a violent wind rolling against them—always from the sun—so as to make it clear that this tail is neither more nor less than the accumulation of this

Fig. 22.—Combination of jets and envelopes (comet of 1861).

sort of luminous vapour, darted off in the first instance towards the sun, as if something raised it up, as if it were exploded by the sun's heat, out of the kernel, and then immediately and forcibly turned back and repelled from the sun."

The Concentric and Excentric Envelopes.

While in Donati's comet we get perhaps the finest exhibition of concentric envelopes successively thrown off from the nucleus towards the sun, in Coggia's comet, on the other hand, we had the most striking instance which has been yet observed in which the envelopes put on an appearance as if they belonged to two different systems of concentric envelopes cutting each other.

It is important here to enter into some details. In Coggia's comet (as observed with Mr. Newall's 25-inch refractor, with a low power), next to the nucleus the most brilliant feature was an object resembling a fan opened out some 160°. The nucleus, marvellously small and definite, was situated a little to the left of the pin of the fan—not exactly, that is, at the point held in the hand. If this comet, outside the circular outline of the fan, offered indications of other similar concentric circular outlines, astronomers would have recognized in it a

[1] Continued from p. 142.

great similarity to Donati's comet with its "concentric envelopes." But it did not do so. Envelopes there undoubtedly were, but instead of being concentric they were excentric, and of an entirely unique arrangement.

To give an idea of the appearance presented by these excentric envelopes, still referring to the fan, let us imagine a circle to be struck from the left-hand corner with the right-hand corner as a centre, and make the arc a little longer than the arc of the fan. Do the same with the right-hand corner. Then with a gentle curve connect the end of each arc with a point in the arc of the fan half-way between the centre and the nearest corner. If these complicated operations have been properly performed, the reader will have superadded to the fan two ear-like things (as of an owl), one on each side. Such "ears," as we may for convenience call them, were to be observed in the comet, and they at times were but little dimmer than the fan. It will be observed that there is a central depression between the ears.

At first it looked as if these ears were the parts of the head furthest from the nucleus in advance along the comet's axis, but careful scrutiny revealed, still further forwards, a cloudy mass, the outer surface of which was convex, while the contour of the inner surface exactly fitted the outer outline of the ears and the intervening depression. This mass was at times so faint as to be almost invisible. But at other times it was brighter than all the other details of the comet which remain to be described, now that I have sketched the groundwork. Occasionally to be seen outside all was still another fainter mass, both the surfaces of which were convex outwards, the inner one having a greater radius. This exterior envelope or "umhullung" was the faintest part of the head.

In the root of the excessively complex tail were to be observed prolongations of all the curves to which I have referred. Thus, behind the brightest nucleus was a region of darkness which opened out 45° or 60°, the left-hand boundary of which was a continuation of the lower curve of the right ear. All the boundaries of the several different shells which showed themselves, not in the head in front of the fan, but in the root of the tail behind the nucleus, were continuous in this way—the boundary of an interior shell on one side of the axis bent over in the head

FIG. 23.—Rough outline sketch of head and envelopes of Coggia's comet as seen in Mr. Newall's 25-inch refractor on the night of July 12, 1874 (perihelion passage, August 27).

to form the boundary of an exterior shell on the other side of the axis.

I next draw attention to the kind of change observed. To speak in the most general terms, any great change in one "ear" was counterbalanced by a change of an opposite character in the other; so that, when one ear was thinned or elongated, the other widened; when one was dim, the other was bright; when one was more "pricked" than usual, the other at times appeared to lie more along the curve of the fan and to form part of it. Another kind of change was in the fan itself, especially in the regularity of its curved outline and in the manner in which the straight sides of it were obliterated altogether by light, as it were, streaming down into the tail.

There was nothing which in the slightest degree resembled the giving off of vapour.

The only constant feature in the comet was the exquisitely soft darkness of the region extending for some little distance behind the nucleus. Further behind, where the envelopes, the prolongation of which formed the tail, were less marked, the delicate veil which was over even the darkest portion became less delicate, and all the features were merged into a mere luminous haze. Here all structure, if it existed, was non-recognizable, in striking contrast with the region round and immediately behind the fan.

Next, it has to be borne in mind that the telescopic object is, after all, only a projection, from which the true figure has to be built up, and it is when this is attempted that the unique character of this comet becomes apparent. There were no jets, there were no concentric envelopes; but, in place of the latter, excentric envelopes indicated by the ears and their strange backward curvings, and possibly also by the fan itself.

It seems impossible that we can be here dealing with the mere volatilization of the materials of which the nucleus is composed; for, assuming that it is possible, as has hitherto been imagined, that shells of vapours can be thrown off to form concentric envelopes, and that the heads of comets like Donati's are thus built up, it is difficult at first to see how such appearances as here described could be thus produced.

On the Forces which produce the Various Forms and Parts of Comets.

Before we proceed further with any detailed description, it is necessary to inquire into the causes of the cometary phenomena with which we have so far become acquainted—namely, nucleus, jets, envelopes concentric and excentric, and tails.

We shall best do this by referring to the various memoirs with which Roche, of Montpellier, has enriched science. He dealt first with the atmospheres of planets; and, in concluding the third part of a memoir on the figure of a fluid mass subjected to the attraction of a distant point,[1] remarked that the inquiry might possibly apply to the theory of comets, if we suppose such an object, fluid and homogeneous, falling in a straight line towards the sun.

We have seen that a comet when it first makes it appearance at its greatest distance puts on a form resembling a planetary nebula. It is at this point that M. Roche closes with it in order to see what its change of form must be supposing it to be as above stated fluid and homogeneous.

As it approaches the sun, a tidal action will be set up, as the solar attraction will be greater on the particles nearest to it; hence there will be an elongation of the swarm, and possibly even one or more separations along a radius vector.

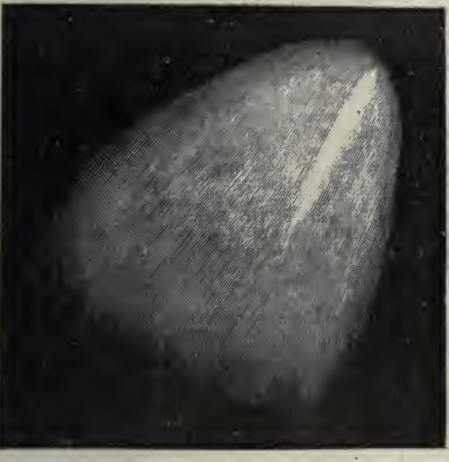

FIG. 24.—Elongation of a cometary swarm. Comet 1882 *b*, Washington equatorial.

If gravitation alone is concerned, the comet will remain symmetrical, it will reduce its size as it approaches the sun,[2] and part of its outer portions will be successively lost along the radius vector both towards and away from the sun; there, in fact, will be two outpouring streams—one directed towards the sun, the other away from it. There will be the greatest elongation and the greatest loss at perihelion.

M. Roche makes this out by considering the form of the envelope in which particles will be equally attracted by the sun and the general mass of the comet.

One chief point of the mathematical investigations was, in fact, to determine the surface on which the gravity of a small particle was *nil* in consequence of the solar and cometary attractions. This is called the limiting surface. On this point I quote from M. Faye:—[3]

"There exists, for every body placed within the sphere of action of our sun, a surface limit beyond which its matter may not pass, under pain of escaping to that body and falling within the domain of the solar action. This surface limit depends on two things—the mass of the body, and its distance from the sun. For a planet like the earth, whose mass is so considerable, this surface limit is very distant, and yet, within the still terrestrial region of its satellite, the moon, a child could lift, without much difficulty, a body which would weigh for us 36,000 kilogrammes, so feeble does the attraction of our globe become at that distance of 60 terrestrial radii. A little beyond the lunar orbit, a body would cease to belong to the earth, and would enter the exclusive domain of the sun. But for a comet this surface limit is much nearer the nucleus, and, moreover, it draws nearer and nearer in proportion as the comet approaches the sun. . . . The surface which so limits a body in the vicinity of the sun presents two singular points in the direction of the radius vector, setting out from which this surface is widened out into a conical network, in such a manner that the dissolution of a body the matter of which reaches or passes beyond these boundaries is effected principally in the vicinity of the points referred to, flying, so to speak, into two pieces, thus obeying at once the attraction of the comet and especially, the thenceforth preponderating attraction of the sun. . . .

FIG 25.—Showing how a comet approaching the sun, gravity alone being in question, loses its constituent particles beyond its free surface, which is constantly diminishing, by an outflow in both directions along the radius vector.

"All the conditions of instability are found united in comets. Their mass is extremely small, and, consequently, the surface limit is very near the centre of gravity. Their distance from the sun diminishes rapidly in the descending branch of their trajectory; consequently this surface limit becomes more and more contracted. Finally, their enormous volume tends unceasingly to dilate, because of the increasing heat of the sun, and to cause the cometary matter to shoot out beyond this surface limit.

"What becomes of this matter after it is set free by the action of the sun? Having escaped from that of the comet, it will none the less preserve the original speed, *i.e.* the speed which the comet itself had at the moment of separation; this speed will scarcely be altered by the feeble attraction of the cometary nucleus, or by the internal movements of which I have spoken, since these are measured by a few metres per second, while the general motion round the sun takes place at the rate of 10, 15, 20 leagues and more per second. The molecules, separated and thenceforward independent, then describe isolated orbits around the sun, differing very little from that of the comet. Those which are found in advance go a little faster and take the lead; those which are behind remain a little in the rear; so that the abandoned materials are divided along the trajectory of the comet in front and in rear of the nucleus In time these materials are separated considerably from the body from which they emanate, and are more and more disseminated; but, considered at the moment of emission, they will form two visible appendages, two sorts of tails opposed and stratified on the orbit of the comet."

So much for the state of things if gravitation alone is in question.

But is gravitation alone concerned in building up a comet's form? That this is not so was fully recognized long ago, and it was suggested by the fact that the tails always appeared to be driven away from the sun; Seneca, indeed, was possibly acquainted with this fact, as he wrote: "Comæ radios solis effugiunt."[1] Kepler was the first to suggest that the matter of the tails was transported to the regions opposite the sun by the impulsion of the solar rays; Euler and Laplace accepted this explanation; and Newton was the first to give a complete explanation of the curve of the tail.

Olbers, whose researches dealt with the phenomena presented by the comet of 1811, considered that the approach of a comet to the sun might develop electricity in one or the other of these bodies, and to this were ascribed both the repulsive action of the

[1] See Pliny, Book II. chap. xxii. *et seq.*, for many references to more ancient authorities.

sun on the materials of the comet, and that of the comet on the nebulous atmosphere by which it was surrounded.

Olbers was driven to consider the repulsive action of the comet on its atmosphere in order to explain the many luminous sectors visible in the comet in question. To this he also ascribed the gradual rise of successive envelopes, so well illustrated subsequently by the comet of Donati.

The energy of electrical repulsion depends upon the amount of surface of the bodies concerned, whereas the attraction of gravity depends upon the masses of the bodies. Small things have more surface in proportion to their masses than large ones, and there will therefore be attraction or repulsion between the sun and the particles composing comets according as the differential effect of the two opposite forces is repulsive or attractive. In the very small particles, the electrical repulsion will be stronger than the attraction due to gravitation, while in the larger particles the two forces may balance each other, or gravitation may preponderate. Only the finest particles composing the head of a comet are therefore repelled to form the tails.

Bessel[1] considerably modified this hypothesis. He considered that the action of the sun on the comet represented a polar force.

M. Faye has more recently held that this repulsive action is due to the radiant energy of the sun, and that it has an intensity inversely as the square of the distance, and proportional to the surface and not to the mass of the moving particles. Its action would therefore be in the inverse ratio of the density of the particles upon which it acted; it would vary with every difference of cometary constitution; it would be inappreciable on the nucleus itself; (the idea being, of course, that the nucleus was a solid body); and it would be most effective in the case of the rarest vapours. The important part of M. Roche's later memoir consists in testing these views of repulsion, to determine whether the forms of comets could be explained by its introduction.

One result is very striking: the tail towards the sun demanded by gravitation alone at once disappears. The limiting surfaces which Roche's calculations demand are so very like some of the surfaces actually observed in the head of a comet, where they can be best seen, that it is suggested that the movement of the particles takes place in the precise direction where they would flow according to M. Roche's mathematical investigations.

Hence we are justified in attributing some cometary phenomena to the flow of matter acting under the influence of attraction and solar repulsion.[2] In concluding his memoir Roche points out (p. 393) that the hypothesis of a repulsive force acting along a radius vector, and varying inversely as the square of the distance, and only acting on matter reduced to a state of great rarefaction, gives figures identical with those observed. We see the germ of the tail is the part of the atmosphere the furthest removed from the sun, and it is easy to explain the enormous development of the emission of cometary particles near perihelion. The existence of a repulsive force which counterbalances the solar attraction M. Roche therefore considers established by his researches.

It must, however, be at once stated that much remains to be done before all the help that M. Roche's work can afford can be

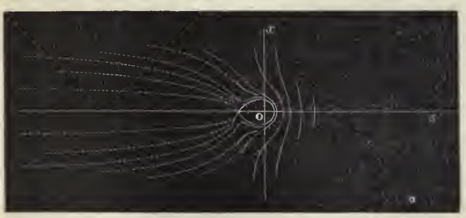

Fig. 26.—M. Roche's theoretical construction of the head of a comet, a repulsive force being taken into account.

utilized, and there is little question that the outflow in the solar direction has not been so entirely abolished as his figures indicate. This, however, may to a certain extent depend upon the fact that the observations of comets have been made at some distance from perihelion. But there may be another reason. If the outflow along the limiting surface is an outflow of solid particles, the solar repulsion will not be effective until collisions have reduced this dust to vapour. We shall still therefore have the quasi-conical surface *turned towards the sun*,[1] though it will be soon destroyed. Many of the phenomena presented by jets and excentric envelopes may be thus caused, and the very complicated phenomena presented by Coggia's comet, and others in which the section of the cone presents the appearance of birds with their wings more or less extended, do not seem opposed to this view.

J. Norman Lockyer.

(*To be continued.*)

[1] Although this does not figure in Roche's diagrams, Faye gives it in his lectures on the "Forms of Comets."

PRELIMINARY NOTE ON KEELING ATOLL, KNOWN ALSO AS THE COCOS ISLANDS.

Mr. John Murray, of the *Challenger* Expedition Office, has forwarded to us the following letter, which he has received from Dr. Guppy:—

Dear Mr. Murray,—

During my sojourn of nearly ten weeks in these islands, I was able to make a fairly complete examination of them. Here, I can only refer to some of the new features of this atoll which my investigations have disclosed, and must leave the details to be subsequently worked into a general description of the islands. Regarding myself as very fortunate in being able to examine the only atoll visited by Mr. Darwin—the atoll, in fact, which gave rise to the theory of subsidence—I at once set about making observations, without reference to any particular view of the origin of coral-reefs. I examined all the islands and islets, more than twenty in number, making a separate description of each, and reaped the benefit of the fact that this atoll has been occupied for more than half a century by residents interested in their surroundings. The result has been to convince me that several important characters of these islands escaped the attention of Mr. Darwin, partly owing to his limited stay, partly also due to his necessarily defective information of the past changes in the atoll. The features, in fact, that escaped his notice, throw considerable light on the mode of origin of these lagoon islands, and give no support to the theory of subsidence.

In the first place, I have ascertained that Keeling Atoll consists essentially of a ring of horse-shoe or crescentic islands inclosing a lagoon and presenting their convexities seaward. The crescentic form is possessed in varying degrees by different islands: some of the smaller ones are perfect horse-shoe atollons, and inclose a shallow lagoonlet; others, again, exhibit only a semi-crescentic form; whilst the larger islands have been produced by the union of several islands of this shape. The whole land-surface, however, is subject to continual change. The extremities of islands are often being gradually swept away or extended. Some islands are breached during heavy gales, others are joined, so that by the repetition of these changes the island in the course of time loses its original form. Hence it is that, although the crescent is the primitive shape of each island this structure is partly disguised in the case of some of the larger islands by the union of several of smaller size. The Admiralty chart gives but an imperfect idea of the true shape of the islands; but, notwithstanding, its inspection will prove very instructive.

In truth, Keeling Atoll exhibits in an incomplete manner the features of the large compound atoll of the Maldive Group. If it was considerably larger and possessed a less protected lagoon, so that open-sea conditions prevailed in its interior, it would have all the features of a compound Maldive atoll—that is, an atoll consisting of a circle of small atolls or atollons. In its original condition, however, it was an atoll consisting of a circle of crescentic islands. Such it is essentially now, but extensive changes have often partly disguised this feature.

Before proceeding to explain the origin of the incompleted compound atoll of the Keeling Islands, it will be necessary to dwell on the exaggerated prevailing notion of an atoll. This kind of coral-reef is usually described as a circular reef inclosing a deep basin or lagoon; but this description only applies to very small atolls less than a mile across. By drawing a section on a true scale of an atoll of average size, like Keeling Atoll, it will at once become apparent that such a description

gives a very misleading idea of the real nature of this class of reef. A section of Keeling Atoll, drawn from the 1000-fathom line on a true scale of an inch to the mile, and intended to illustrate a breadth of six miles, and a depth in the lagoon of 9 or 10 fathoms, would represent to the naked eye a flat-topped mountain, the depth of the so-called basin on the summit being merely represented by a slight central depression of about 1/100 of an inch. If the lagoon possessed a depth of 30 fathoms, the inclosed basin so-called would only be indicated in this section by a central depression of about 3/100 of an inch. So trifling a proportion does the depth of an atoll of ordinary size bear to the breadth, that such a reef can only be accurately described as possessing a broad level surface, with very slightly raised margins. A correct model of Keeling Atoll would at once convey a just idea of the true relative dimensions of a reef of this class. The lagoon would be there only represented by a film of water occupying a slight hollow in the level mountain-top. By thus grasping these facts, we at once perceive that by reason of our failing to view an atoll in relation to its surroundings, and through our misconceptions of its dimensions, we have been led to introduce a great cause to explain a very small effect. The slightly raised margins can be easily explained by causes dwelt upon by Murray, Agassiz, and others. No movement of the earth's crust is necessary for this purpose. The mode of growth of corals, the action of the waves, and the influence of the currents, afford agencies quite sufficient to produce the slightly raised margins of an atoll.

The development of the islands of an atoll into horse-shoe or crescentic islands, as in the instance of Keeling Atoll, or into perfect small atolls or atollons, as in the Maldive Group, is a subsequent process to be shortly explained. These small atolls and horse-shoe islands only assume their characteristic forms *after the island has been thrown up by the waves.* Such was the conclusion I arrived at concerning small atolls and crescent-shaped coral islands in the Solomon Islands (Proc. Roy. Soc. Edin., 1885–86, p. 900); and as just stated I have formed the same opinion concerning the islands of Keeling Atoll. There is in the first place the island from which "lateral extensions grow out on either side so as to ultimately form a horse-shoe reef," which itself under favourable conditions may develop into a small atoll. In the Solomon Islands I imperfectly grasped the method by which these changes in form are effected. In Keeling Atoll I saw the process in operation, and I arrived at the conclusion that wherever a coral island stems a constant surface-current, the sand produced by the breakers on the outer edge of the reef will mostly be deposited by the current on each side of the island in the form of two lateral banks or extensions, giving the island ultimately a horse-shoe form, with the convexity presented against the current. The process may be aptly compared to the formation of a V-shaped ridge of sand when a stake or some other obstacle is placed in a river-bed. The stake represents the original small island thrown up by the waves. The V-shaped ridge of sand represents the arms of the horse-shoe island which are subsequently formed. The back-wash or eddy may in the river-bed join the arms of the V-shaped ridge of sand. In a similar manner a horse-shoe island may have a bank thrown up across the mouth, and thus a small atoll is formed. Such is the process, imperfectly disclosed to me in the Solomon Islands, that I found illustrated in all its stages in Keeling Atoll. In the Keeling Islands, however, it was necessary to satisfy myself of the reality of the agencies chiefly concerned in this process. For instance, I had to ascertain how and to what extent the surface-currents acted, and to discover the source of the sand. It was also necessary to observe what changes in the form and extent of the islands had occurred in the experience of the residents during the half-century of their occupation.

The westerly equatorial drift or south-east trade current, striking the south-east angle of the atoll, there divides and sweeps around the coasts, the two branches meeting and forming an eddy off the north-west island, a spot where drift timbers are often detained and stranded after having been swept around half the circumference of the atoll. Advantage of this current is taken by the proprietor of the islands, who directs his men to mark any logs of valuable timber thrown up on the weather or south-east coast, and then to launch them again outside the breakers. In this way huge logs are transported by the current to any particular island. If left alone, the logs, whether drifted around the north or south side of the atoll, arrive finally in the eddy off the north-west angle. This current finds its way into the lagoon through the several passages between the islands its rate there varying usually from half a knot to two knots in the hour. Only rarely is there any check to the inflow of water through the passages, as, for instance, during north-west gales.

The current in these passages carries daily a large amount of sand into the lagoon. I discovered this accidentally whilst using the tow-net for catching the pelagic animals brought in by the current. The source of this sand is the weather edge of the reef on the outer side of the islands, where the breakers are unceasingly at work in keeping up the supply. After several measurements under varying conditions of current, tide, and depth, I estimated that during every day of ordinary weather at least 10 tons of sand are carried through the passages into the lagoon. During gales and cyclones this amount is greatly increased; and probably the estimate for an ordinary year would not be less than 5000 tons. The bulk of this sand is deposited by the current near the inner mouths of the passages and on the margins of the lagoon, where it goes to extend the islands in the form of banks stretching into the lagoon. In this manner an island obtains a horse-shoe shape, just as the V-shaped ridge is formed by placing a stake in a river-bed. The first stage is represented by an island with two sand-banks extending into the lagoon, one from each extremity. The second stage is that in which the island has attained a semi-crescentic shape by the encroachment of its vegetation on the newly formed banks. In the course of time, when the vegetation of the island has entirely occupied the banks, the third stage, that of the horse-shoe island, is reached. In some instances, there is yet a further stage, when during a long continuance of westerly winds another bank is thrown up across the mouth of the horse-shoe, and a small atoll with a shallow lagoonlet is produced. Thus the currents are the principal agencies in forming the horse-shoe islands of Keeling Atoll. In large atolls, where more open-sea conditions prevail in the lagoon, and especially where, as in the Maldives, there are two opposite sets of winds and surface-currents, each prevailing in its own half of the year, we should expect to find the horse-shoe island replaced by an atollon. Keeling Atoll, however, lies for eleven months out of the twelve within the region of the constant trade-wind and westerly drift current, so that the situation is only one favouring the formation of horse-shoe islands facing to the southward and eastward. The protected character of the lagoon, also, is not a condition that would assist the growth of a circular island or atollon.

Another important feature in this atoll is to be found in the existence outside the seaward edge of the present reef of a series of submerged lines of growing corals separated from each other by sandy intervals. Unfortunately, I was not able to examine these to the extent I desired, since it can only be satisfactorily done later in the year, when the sea is sufficiently smooth to allow boats to approach the breaker edge of the reef. This feature, however, is familiar to the residents, who have supplied me with information on the subject. It would seem that all around the circumference of this atoll there is a space outside the present edge of the reef varying from 200 to 500 or 600 yards in width, where ships have anchored, and where boats in the calm season go with fishing parties. Here the submarine slope slopes gradually down to 20 or 30 fathoms; but beyond this the descent is precipitous. It is on this gradual slope that the lines of growing coral occur, separated by sandy intervals from each other. There may be two or three of these lines, the innermost covered by 4 or 5 fathoms, and the outer by from 20 to 30 fathoms.

We are thus able to perceive that the outward extension of the reef is effected, not so much by the seaward growth of the present edge of the reef, as by the formation outside it of a line of growing corals, which when it reaches the surface reclaims, so to speak, the space inside it, which is soon filled up with sand and reef-*débris.* The evidence, in fact, goes to show that a reef grows seaward rather by jumps than by a gradual outward growth. This inference is of considerable importance, since it connects all classes of reefs together in the matter of their seaward growth, the degree of inclination of the submarine slope being the chief determining factor.

Following Le Conte, I have previously shown (Proc. Roy. Soc. Edin. 1885–86, p. 884) that where there is a very gradual submarine slope the deposition of sand and the presence of much sediment in the water will prevent the growth of corals in the shallow water outside the seaward edge of the reef, and that in consequence a line of living corals will spring up in the clearer and deeper waters a considerable distance beyond. The appearance of this line of coral at the surface will result in the production of a barrier-reef with a lagoon-channel inside. In

a similar manner the submerged line of growing corals immediately outside the weather-edge of the reef of Keeling Atoll would form a barrier-reef, if it was removed some miles from the shore instead of being only about 100 yards distant. As it is now situated, it lies too close to the edge of the present reef to prevent the obliteration of the channel inside it after it has reached the surface. Its lagoon-channel would be very quickly filled with sand and reef-*débris*, and as a result we should merely have a permanent addition to the present reef-flat, which, when the process was complete, would be 100 yards wider. The process is the same as in the case of a barrier-reef, the difference in the result being due to the submerged line of corals being too close to the edge of the reef for the preservation of the interior channel; and this circumstance is due to the fact of the submarine slope being greater than in the case of a coast fronted by a barrier-reef. These remarks are merely intended to be suggestive. They may, perhaps, direct the attention of of other observers to the examination of the outer slopes of atolls and to their mode of seaward growth. This can only be done during unusually calm weather.

I have discovered many other new features of minor interest in connection with Keeling Atoll, to which I will refer in my full description of these islands. The island of North Keeling, lying fifteen miles to the north, is a small atoll connected with Keeling Atoll by a bank. I hope to describe it at some future time.

In conclusion, I may state that most of my observations in these islands were directed towards estimating the age of Keeling Atoll. These data have yet to be worked up, and I am fairly confident of getting a satisfactory estimate. The lagoon is rapidly filling up with sand and coral, but it is almost impossible to state in precise terms the changes since the visit of the *Beagle*, as the survey then made was little more than a sketch. The present Admiralty chart is of but little service in inquiring into past changes, for in it the original survey of the *Beagle* in 1836 has received several later additions, and there is nothing to distinguish the one from the other. For the purpose of navigation, and for the advantage of science, a complete examination of these islands should be made. The best season for surveying is during the calm weather of the months of January and February, when boats can venture close to the edge of the reef, and a satisfactory examination of the outer shores, as well as the interior of the atoll, can then be made. In collecting information from the residents, it will be necessary to remember that no records are kept in the islands; and in studying past changes the observer will have to receive what may at first sight appear to be very interesting facts with scientific caution. Some corroboration of such facts should always be looked for.

Yours faithfully,

Batavia, November 8. H. B. GUPPY.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 20, 1888.—"Correlations and their Measurement, chiefly from Anthropometric Data." By Francis Galton, F.R.S.

Two organs are said to be co-related or correlated, when variations in the one are generally accompanied by variations in the other, in the same direction, while the closeness of the relation differs in different pairs of organs. All variations being due to the aggregate effect of many causes, the correlation is a consequence of a part of those causes having a common influence over both of the variables, and the larger the proportion of the common influences the closer will be the correlation. The length of the cubit is correlated with the stature, because a long cubit usually implies a tall man. If the correlation between them were very close, a very long cubit would usually imply a very tall stature, but if it were not very close, a very long cubit would be on the average associated with only a tall stature, and not a very tall one; while, if it were *nil*, a very long cubit would be associated with no especial stature, and therefore, on the average, with mediocrity. The relation between the cubit and the stature will serve as a specimen of other correlations. It is expressed in its simplest form when the relation is not measured between their actual lengths, but between (*a*) the deviation of the length of the cubit from the mean of the lengths of all the cubits under discussion, and (*b*) the deviation of the mean of the corresponding statures from the mean of all the statures under discussion. Moreover these deviations should be expressed on the following method in terms of their respective variabilities. In the case of the cubit, all the measures of the left cubit in the group under discussion, and which were recorded in inches, were marshalled in the order of their magnitude, and those of them were noted that occupied the first, second, and third quarterly divisions of the series. Calling these measures Q_1, M, and Q_3, the deviations were measured from M, in terms of inches divided by $\frac{1}{2}(Q_3 - Q_1)$, which divisor we will call Q. Similarly as regards the statures. [It will be noted that Q is practically the same as the probable error.] This having been done, it was found that, whatever the deviation, y, of the cubit might be, the mean value of the corresponding deviations of stature was $0 \cdot 8y$; and, conversely, whatever the deviation, y', of the stature might be, the mean value of the corresponding deviations of the cubit was also $0 \cdot 8y'$. Therefore this factor of 0·8, which may be expressed by the symbol r, measures the closeness of the correlation, or of the reciprocal relation between the cubit and the stature. The M and Q values of these and other elements were found to be as follow:[1] left cubit, 18·05 and 0·56; stature 67·2 and 1·75; head length, 7·62 and 0·19; head breadth, 6·00 and 0·18; left middle finger, 4·54 and 0·15; height of right knee, 20·50 and 0·80; all the measures being in inches. The values of r in the following pairs of variables were found to be: head length and stature, 0·35; left middle finger and stature, 0·70; head breadth and head length, 0·45; height of knee and stature, 0·9; left cubit and height of right knee, 0·8. The comparison of the observed results with those calculated from the above data showed a very close agreement. The measures were of 350 male adults, containing a large proportion of students barely above twenty-one years of age, made at the laboratory at South Kensington, belonging to the author.

These results are identical in form with those already arrived at by the author in his memoir on hereditary stature (Proc. Roy. Soc., vol. xl, p. 42, 1886), when discussing the general law of kinship. In that memoir, and in the appendix to it by Mr. J. D. Hamilton Dickson, their *rationale* is fully discussed. In fact, the family resemblance of kinsmen is nothing more than a special case of correlation.

The general result of the inquiry was that, when two variables that are severally conformable to the law of frequency of error, are correlated together, the conditions and measure of their closeness of correlation admits of being easily expressed. Let x_1, x_2, x_3, &c., be the deviations in inches, or other absolute measure, of the several "relatives" of a large number of "subjects," each of whom has a deviation, y, and let X be the mean of the values of x_1, x_2, x_3, &c. Then (1) $y = r$X, whatever may be the value of y. (2) If the deviations are measured, not in inches or other absolute standard, but in units, each equal to the Q (that is, to the probable error) of their respective systems, then r will be the same, whichever of the two correlated variables is taken for the subject. In other words, the relation between them becomes reciprocal; it is strictly a correlation. (3) r is always less than 1. (4) r (which, in the memoir on hereditary stature, was called the ratio of regression) is a measure of the closeness of correlation. Other points were dwelt upon in the memoir, that are not mentioned here: among these was as follows: (5) The probable error, or Q, of the distribution of x_1, x_2, x_3, &c., about X, is the same for all values of y, and is equal to $\sqrt{(1 - r^2)}$ when the conditions specified in (2) are observed.

It should be noted that the use of the Q unit enables the variations of the most diverse qualities to be compared with as much precision as those of the same quality. Thus, variations in lung-capacity which are measured in volume can be compared with those of strength measured by weight lifted, or of swiftness measured in time and distance. It places all variables on a common footing.

"Preliminary Account of the Morphology of the Sporophyte of *Splachnum luteum*." By J. R. Vaizey, M.A., of Peterhouse, Cambridge. Communicated by Francis Darwin, F.R.S.

[1] The head length is here the maximum length measured from the notch below the brow. The cubit is measured with the hand prone, from the flexed elbow to the tip of the middle finger. The height of knee is taken from a stool, on which the foot rests with the knee flexed at right angles; from this the measured thickness of the heel of the boot is subtracted. All measures had to be made in the ordinary clothing. The smallness of the number of measures, viz. 350, is of little importance, as the results run with fair smoothness. Neither does the fact of most of the persons measured being hardly full grown affect the main results. It somewhat diminishes the values of M, and very slightly increases that of Q, but it cannot be expected to have any sensible influence on the value of r.

Royal Meteorological Society, December 19.—Dr. W. Marcet, F.R.S., President, in the chair.—The following papers were read:—On the prolonged spell of cold weather from September 1887 to October 1888, by Mr. C. Harding. During the fifty-nine weeks ending the third week in October, there were but four warm weeks in the north-west of England, and only five warm weeks in the south-west of England, whilst in the latter district there was not a single warm week between March 12 and October 22. The mean temperature for the whole period was dealt with for the twelve districts into which the Meteorological Office divides the whole area of the United Kingdom, and with the single exception of the north of Scotland the weather for the period ending in October this year was the coldest of any during the past ten years. At Greenwich the temperature during the fourteen months was below the average on 312 days out of 427, or 73 per cent., and in July there was not a single warm day, the temperature being continuously below the average from June 27 to August 6. The means for July 11 and 12 were colder by several degrees than those for March 9 and 10.—Report on the phenological observations for 1888, by the Rev. T. A. Preston. Vegetation was generally backward throughout the season. In the south west of England and south of Ireland plants were earlier than usual, but not elsewhere. In February they were from one to four weeks later, and gradually gained ground till June. In the south of Ireland they were slightly in advance of the average in June and July; in the south-west of England they just reached the average in July; whilst in Guernsey they were a fortnight later. Fruits generally were a failure; very few really ripened, and from want of sun were deficient in flavour. Haymaking was unusually late (as much as five weeks); it began in July or August, and was not entirely finished till late in September; much of it was spoilt or secured in bad condition. Straw was plentiful, and though the corn was not an average crop, the fine October enabled farmers to secure a better one than could have been expected. Roots were often a failure, and potatoes were much diseased.—A winter's weather in Massowah, by Captain D. Wilson-Barker. This paper gives the results of four-hourly observations during December 1887 to February 1888. The highest shade temperature was 95°, and the lowest 68°.

Zoological Society, December 18, 1888.—Mr. Howard Saunders in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of November 1888, and called attention to a specimen of the Small-clawed Otter (*Lutra leptonyx*), presented by Mr. W. L. Sclater, Deputy Superintendent, Indian Museum, Calcutta, new to the Society's Collection, and to a Monkey of the genus *Cercopithecus*, from South Africa, apparently referable to the Samango Monkey (*Cercopithecus samango*), also new to the Society's Collection.—Mr. G. B. Sowerby read descriptions of fourteen new species of Shells from China, Japan, and the Andaman Islands, chiefly collected by Deputy Surgeon-General R. Hungerford.—A communication was read from Mr. Herbert Druce, in which he gave an account of the Lepidoptera-Heterocera collected by Mr. C. M. Woodford in Guadalcanar Island, Solomon Islands. The collection was stated to contain examples of 53 species, 18 of which were described as new to science.—Mr. J. H. Leech read the second portion of a paper on the Lepidoptera of Japan and Corea, comprising an account of the Sphingidæ, Bombycidæ, Notodontidæ, and Cymatophoridæ, in all 352 species. Of these, 38 species were now described as new to science.—Dr. Hans Gadow read a paper on the numbers and on the phylogenetic development of the remiges of Birds. The author showed that the number of primaries is of very limited taxonomic value, as was proved by the numerous exceptions mentioned in the lists contained in the paper. A comparison of the remiges of the Penguins with those of other Carinatæ seemed to indicate an extremely low stage in the Penguins, which, however, was not borne out by other anatomical features. The Ratitæ were most probably descendants of birds which formerly possessed the power of flight and had lost it. This view was strengthened by an examination of the structure of the wings and of the feathers of their nestlings. The paper concluded with general remarks upon the probable gradual development of the organism of flight in birds.

PARIS.

Academy of Sciences, December 17, 1888.—M. Janssen in the chair.—On the analytical theory of heat, by M. H. Poincaré. In a previous note (*Comptes rendus*, civ. p. 1754) the author studied the problem connected with the cooling of a homogeneous and isotropous solid body; here a more satisfactory demonstration is given of the theorem growing out of that problem.—On the abruptly and slowly contracting muscles of the hare, by M. L. Ranvier. A recent experiment is described, which has been carried out for the purpose of studying in the hare the two species of muscles, which in the rabbit differ in colour, structure, and functions, but which in the hare are all alike red.—On M. Zédé's submarine boat, the *Gymnote*, by Admiral Paris. An account is given of the first trial of this boat, recently launched at Toulon, and constructed for the purpose of realizing the suggestions made by M. Dupuy de Lôme on the subject of submarine electric navigation. As this is an engine of warfare, the details of its mechanism are suppressed; but it is stated that the trial more than realized the expectations of its inventor. It works by electricity, with perfect ease, on, and at any desired depth below, the surface, obeys the helm in all positions, fully attains the hoped-for velocity, and its ventilation and lighting are all that can be expected down to a certain depth. By introducing sundry obvious modifications, boats of this description may be turned to the best account for the purpose of scientific marine exploration.—Eocene Echinidæ in the province of Alicante, Spain, by M. Cotteau. The recent explorations of the Eocene formations in this region have yielded as many as 76 species of fossil Echinidæ, grouped in 36 genera, and representing nearly all existing groups of this family. Of the species, 50 are new to science, and some of these are specially interesting, as they belong to extremely rare genera, well deserving the attention of palæontologists, and four of which are quite new. A striking feature of this Eocene Echinidian fauna is the enormous preponderance of irregular over regular forms, the former comprising as many as 67 out of the 76 species here described.—On the nutriment of castaways at sea, by Prince Albert of Monaco. The researches made during the *Hirondelle's* last expedition in the North Atlantic tend to show that the crew of a vessel short of provisions might support life indefinitely if supplied with the proper appliances for capturing the small marine fauna which is found to exist in great abundance in the Atlantic, and probably in all temperate and warm marine waters.—On the diurnal variation of the barometer, by M. Alfred Angot. It is shown that diurnal barometric variation results from the interference of two distinct waves. One of these is exclusively due to the diurnal variation of temperature in the given region, and subject like it to local influences. The other, of semi-diurnal periodicity, is produced by a general cause independent of all local influence; its phase is constant, approximating to 63°, and its amplitude for all regions and all seasons is determined by an equation, whose terms show a certain analogy with those corresponding to the theory of the tides.—On certain new properties and on the analysis of the fluoride of ethyl, by M. H. Moissan. In a previous communication the author showed that ethylfluorhydric ether (ethyl fluoride) was a gaseous body capable of being obtained in a very pure state, and causing ethyl iodide to react on the anhydrous fluoride of silver. Here he describes several other properties of the same substance. Heated to a dull red for several hours in a glass ball, the fluoride of ethyl yields a complex mixture of carburets containing traces only of the fluoride of silicium. Under the action of a weak induction spark the volume increases greatly, yielding hydrofluoric acid, a small quantity of acetylene, and especially ethylene, without depositing carbon. In the presence of a powerful spark, carbon is deposited with formation of acetylene, ethylene, propylene, &c.—On the employment of oxygenated water for the quantitative analysis of the metals of the iron group (continued), by M. Ad. Carnot. Here the author deals more especially with chromium and manganese.—On the reproduction of zircon, by MM. P. Hautefeuille and A. Perrey. Zircon, obtained at a very high temperature by Sainte-Claire Deville and Caron, by making the fluoride of zirconium to act on silica or on silicium fluoride, is here reproduced at a temperature not exceeding 700° C. by the action of the bimolybdate of lithin on a mixture of zircon and silica. This is the same process by means of which these chemists have obtained the emerald and phenacite.—Papers are contributed by M. Raoul Varet, on the action of the cyanide of mercury on the salts of copper; by M. Albert Colson, on a diquinolic base; by M. W. Louguinine, on the heats of combustion of the camphors and borneols; by M. Louis Crié, on the affinities of the Jurassic and Triassic floras of Australia and New Zealand; and by M. Michel Hardy, on the discovery of a Quaternary burial-place at Raymonden, in the commune of Chancelade, Dordogne.

December 24.—M. Janssen in the chair.—After the usual annual allocution pronounced by the President, M. Janssen, the names were announced of the successful competitors in the prize essays proposed for the year 1888. These were as under:—*Geometry:* Grand Prize of the Mathematical Sciences, M. Emile Picard; Prix Bordin, Madame Sophie de Kowalewsky; Prix Francœur, M. Emile Barbier; Prix Poncelet, M. E. Collignon. *Mechanics:* Extraordinary Prize of 6000 francs, MM. Banaré, Hauser, and Reynaud, 2000 francs each; Prix Montyon, M. H. Bazin; Prix Plumey, Madame Benjamin Normand and family; Prix Dalmont, M. Jean Resal. *Astronomy:* Prix Lalande, M. Joseph Bossert; Prix Valz, Mr. E. C. Pickering; Prix Janssen, Dr. William Huggins; Prix Damoiseau, not awarded. *Statistics:* Prix Montyon, M. Félix Faure, M. J. Teissier, and MM. Lallemand and Petitdidier. *Chemistry:* Prix Jecker, M. Maquenne and M. Cazeneuve. *Geology:* Prix Cuvier, M. Joseph Leidy. *Botany:* Prix Desmazières, M. V. Fayod; Prix Montagne, M. Gaston Bonnier. *Agriculture:* Prix Vaillant, not awarded. *Anatomy and Zoology:* Prix Savigny, not awarded; Prix Thore, Dr. Carlet; Prix da Gama Machado, not awarded. *Medicine and Surgery:* Prix Montyon, Dr. Hardy, Dr. Albert Hénocque, and MM. Follin and Duplay; Prix Bréant, Dr. Hauser; Prix Barbier, MM. Leroy, Raphael Dubois, and Dr. Ehrmann; Prix Godard, Dr. Maurice Hache; Prix Lallemand, MM. François-Franck and Paul Blocq. *Physiology:* Prix Montyon, Dr. Augustus D. Waller (London) and M. Léon Fredericq. *Geography:* Prix Gay, M. Simart. *General Prizes:* Prix Montyon (Unhealthy Industries), Dr. Paquelin and M. Fumat; Prix Trémont, M. Fénon; Prix Gegner, M. Valson; Prix Delalande-Guérineau, Père Roblet; Prix Jérome Ponti, M. Kœnigs; Prix Laplace, M. Paul-Louis Weiss.—The programme of prizes proposed for the year 1889 comprises the following:—*Geometry:* Prix Francœur (1000 fr.), discoveries or works useful to the progress of pure or applied mathematical sciences; Prix Poncelet (2000 fr.), same subject. *Mechanics:* Extraordinary Prize of 6000 francs for any invention tending to increase the efficacy of the French naval forces; Prix Montyon (700 fr.), invention or improvement of instruments useful to the progress of agriculture, the mechanical arts or sciences; Prix Plumey (2500 fr.), any invention or improvement tending most to the progress of steam navigation; Prix Fourneyron (500 fr.), theoretical and practical essay on the progress of aërial navigation since 1880. *Astronomy:* Prix Lalande (540 fr.), any essay or observation most useful to the progress of astronomy; Prix Valz (460 fr.), the most interesting astronomical observation during the year; Prix Janssen (gold medal), any discovery or work tending to the progress of physical astronomy. *Physics:* Prix L. La Caze (three of 10,000 fr. each), the best work on physics, chemistry, and Physiology. *Statistics:* Prix Montyon (500 fr.), the best work on the statistics of France. *Chemistry:* Prix Jecker (10,000 fr.), any work tending most to the progress of organic chemistry. *Geology:* Prix Delesse (1400 fr.), best work on geology or mineralogy. *Botany:* Prix Barbier (2000 fr.), most useful discovery in medicine, surgery, pharmacy, or botany; Prix Desmazières (1600 fr.), the most useful work on all or any section of Cryptogamy; Prix Montagne (1000 and 500 fr.), useful works on the anatomy, physiology, development, or description of the lower Cryptogamous plants; Prix de la Fons Mélicocq (900 fr.), best work on the botany of North France. *Agriculture:* Prix Vaillant (4000 fr.), best work on the diseases of cereals in general. *Anatomy and Zoology:* Grand Prix des Sciences Physiques (3000 fr.), the complete study of the embryology and development of any animal; Prix Bordin (3000 fr.), a comparative study of the auditory apparatus in mammals and birds; Prix Savigny (975 fr.), in aid of young zoologists studying the invertebrates of Egypt and Syria. *Medicine and Surgery:* Prix Montyon (one or more prizes not otherwise specified), for the best work on the healing art; Prix Bréant (100,000 fr.), for a specific against cholera; Prix Godard (1000 fr.), anatomy, physiology, and pathology of the genito-urinary organs; Prix Lallemand (1800 fr.), researches on the nervous system in the widest sense of the term; Prix Ballion (1400 fr.), any work most useful to the health and improvement of the human race; Prix Mège (10,000 fr.), to continue and complete the essay of Dr. Mège on the causes that have retarded or advanced the progress of medicine. *Physiology:* Prix Montyon (750 fr.), for the promotion of experimental physiology; Prix Pourat (1800 fr.), experimental researches on muscular contraction; Prix Martin-Damourette (1400 fr.), therapeutic physiology. *Physical Geography:* Prix Gay (2500 fr.), comparative study of the floras and faunas and relations existing between the Polynesian Islands and surrounding lands. *General Prizes:* Prix Montyon, one or more prizes for the best means of rendering unhealthy industries less dangerous; Prix Trémont (1100 fr.), for any work tending in any way to promote the interests of France; Prix Gegner (4000 fr.), to promote the positive sciences; Prix Petit d'Ormoy (10,000 fr.), researches in pure and applied mathematical sciences and the natural sciences; Prix Laplace (a complete collection of the works of Laplace), the first student leaving the Ecole Polytechnique.

Astronomical Society, November 7.—M. Moussette in the chair.—Colonel Laussedat read a paper on national time, in which he urged the adoption of Paris time throughout France.—M. Gunziger observed Barnard's comet on November 4. It was about the size of the nebula in Andromeda, with scarcely any tail, but a bright nucleus of about the sixth magnitude.—Rev. S. J. Perry, of Stonyhurst College, was elected an honorary member.—The Royal Astronomical Society and the Liverpool Astronomical Society were elected Corresponding Societies.

December 5.—M. Flammarion, President, in the chair.—The President announced that important gifts had been offered for the Society's proposed Observatory: M. Bardou offered a 4-inch equatorial, M. Secretan a transit instrument, M. Lütz spectroscopic and photographic apparatus, M. Lévy a set of binocular glasses. Thanks were voted to the above donors.—M. Flammarion read a paper on the changes observed in Mars, specially referring to Dawes's forked bay and Lake Mœris.—M. Gérigny read a paper on the aberration of light, showing the influence of the sun's motion upon that phenomenon by Yvon Villarceau's method.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Boilers: their Construction and Strength: T. W. Traill (Griffin).—Our Fishery Rights in the North Atlantic: J. I. Doran (Philadelphia).—Methods of Analysis of Commercial Fertilizers, Cattle Foods, &c. (Washington).—The Probable Cause of the Displacement of Beach Lines: A. Blytt (Christiania).—Bulletin of the New York State Museum of Natural History, Nos. 4, 5, 6 (Albany).

CONTENTS.

THURSDAY, JANUARY 10, 1889.

THE LATE WILLIAM DENNY.

The Life of William Denny, Shipbuilder, Dumbarton. By Alexander Balmain Bruce. With Portrait. (London: Hodder and Stoughton, 1888.)

THE late William Denny was in many ways a remarkable man. He was a prominent member of the modern school of naval architects; an ardent advocate of scientific progress in the design and construction of ships; a strong supporter of scientific education in naval architecture; a contributor of many papers and technical data to the various professional institutions of which he was a member; and an eloquent, indefatigable, and effective exponent of his views upon all subjects. He was also the managing partner of one of the largest shipbuilding firms in the world, and was distinguished for his intimate knowledge of the many and intricate details of the business; for his clear insight into, and close grip of, the questions with which he had to deal; for his eager desire to promote good relations among the members of the firm and the various grades of workpeople in their employ; and for what he did all round towards making the business with which he was connected—as he frequently said it was his ambition to do—"a model of efficiency on all sides." Both by practice and by precept, William Denny laboured strenuously and effectively, at all times and seasons, for the advancement of his profession, and for the good of those who wished to qualify themselves for the practice of that profession.

The description of Mr. Denny's work as a naval architect occupies only a comparatively small portion of the present book—108 pages out of 478. The remainder consists of general biographical details, and accounts of Mr. Denny's views upon the many local, and the various political, social, moral, and religious questions in which he had a strong—we may say a burning—and ever-increasing interest. This general record of his acts and words will be valued by those who knew the man, and who admired and loved him—as none who really knew him could help doing—and will give to others who may read it a good idea of a life which was full of activity, interest, and promise.

It is, however, the professional work of the subject of this memoir, and not his vigorous, cultured, many-sided, full, and keenly sympathetic mind and life, that we have to do with here. Prof. Bruce, the author, says that the five chapters (VI.–X.) which deal with this branch of his subject "present a popular account of Mr. Denny's technical work, written by one who possesses no knowledge of the technic of shipbuilding." But they do much more than that, as will be inferred from the fact that Prof. Bruce availed himself of assistance by such competent authorities as Mr. Robert Duncan, the well-known Port Glasgow shipbuilder; Mr. Martell, the Chief Surveyor of Lloyd's Register Society; and Mr. F. P. Purvis, the Chief of the Scientific Department in Messrs. Denny's shipyard.

The name of Mr. Denny is inseparably associated with modern progress in scientific naval architecture. Prof. Bruce says truly that "in naval architecture he was sometimes in fact, and always in spirit, a pioneer, . . . sagacious to discern quickly the value of a new suggestion or invention, prompt to give it generous recognition, energetic and enthusiastic in taking it up and developing it until it had gained a secure place in general thought and practice;" and he "was of that earnest temper that must and will improve where improvement is possible."

Mr. William Denny belonged to a family of shipbuilders. "He was the third in succession of three Williams, of whom the two first, his grandfather and his uncle, had been men of genius in the art of shipbuilding." His grandfather started shipbuilding on his own account in Dumbarton, in 1817, when there was no shipbuilding yard on the Clyde above Dumbarton. He gained renown, during the infancy of steam navigation, as the builder of the Thames passenger-steamer *Marjory*, and of the mail-steamer *Rob Roy*, the first sea-going steamer built, which was employed at first in the Glasgow and Belfast trade, and afterwards as a passenger-vessel between Dover and Calais. He also built the *Trinidad*, the first steamer sent to the West Indies. This William Denny had seven sons, all of whom became shipbuilders. The sole survivor of the seven is Mr. Peter Denny, the father of the subject of this memoir, and the head of the shipbuilding firm of Messrs. William Denny and Brothers, and of other important commercial undertakings, whose long and honourable career and high personal qualities have obtained for him, to an unusual degree, the confidence and esteem of all who know him. Mr. Peter Denny's brother William started the present firm of William Denny and Brothers in 1844. He applied himself with great skill and success to the use of iron in shipbuilding, and in ten years he created a prosperous business. His death occurred at the same early age as that of his nephew, viz. not quite forty years.

The late Mr. William Denny's contributions to the science of naval architecture relate mainly, though not entirely, to the resistance, speed, and propulsion of ships, the stability of ships, the use of steel in construction, and to improvements in structural details and arrangements He was struck by the report of the British Association Committee in 1869—and particularly by the separate report of Mr. Froude—upon the subject of resistance, and the best way of determining by experiment the relation between speed and power in ships. Mr. Froude enunciated in his separate report the law which connects speed with resistance in floating bodies of varying size but similar forms, and enables the resistance of a full-sized ship to be calculated from that of a small model. He also showed graphically, in the shape of curves, the true variation of resistance with speed, as determined by experiment, for ship-shape models of various forms. Both these points were seized hold of and utilized at once by Mr. Denny for practical application. In January 1870, he commenced to test the speeds of steamers progressively on the measured mile, *i.e.* to determine the relation between engine power and speed at several speeds from the lowest to the highest, and to plot curves, similar to those made by Mr. Froude from model experiments, that showed the true variation of power with speed over the whole practicable range of

speed, in the vessels so tried. Previous to that time it had been generally considered that it was sufficiently accurate for ordinary purposes to ascertain the power necessary to drive a ship at one or two different speeds only, and to assume that the resistance at other speeds would vary as the square of the speed. The errors often involved by this assumption were known to be considerable; but the practice was not improved upon until the introduction of Mr. Froude's curves of resistance for models, and Mr. Denny's corresponding curves for actual ships.

In 1873, Mr. Denny entered into correspondence with Mr. Froude, and communicated to him from that time forward the results of his experiments upon the speed of ships. Those results, when compared with what were given by model experiments, were of great assistance to Mr. Froude in his investigations. Mr. Froude said, at the Institution of Naval Architects, in 1876: "Mr. Denny's horse-power results, when closely scrutinized, were found at once to supply most important information on the subject of engine friction; and they have helped to corroborate and further elucidate certain general conclusions on the subject of the expenditure of power in propulsion, which other less crucial tests had enabled me to arrive at approximately." Mr. Froude read a paper, from which the foregoing is a quotation, in which he used the data referred to for determining the ratio of indicated to effective horse-power in ships. He also read a second paper, at the same meeting, in which he said that "the trial of Mr. Denny's ship *Merkara*, referred to in the paper I have already read, furnished materials for extending and giving practical completeness to a comparison [of the resistances of long ships of several types] which our series of experiments had already led us to institute between several types of form." This furnishes an excellent illustration of how progress may be facilitated by the close co-operation of the scientific investigator and experimentalist with the practical worker who requires to understand and apply the teachings of science; and it is one proof out of many of the scientific value of Mr. Denny's early speed trials, and of his readiness to communicate freely the results to others interested in the subject. Mr. Denny laboured with great enthusiasm to perfect the data obtained on measured mile trials of ships, and to collect and record it systematically; and he was always ready to place such information at the disposal of other workers in the same field.

Mr. Denny read a paper, in 1875, before the Institution of Engineers and Shipbuilders of Scotland, on "The Difficulties of Speed Calculations," in which he strongly insisted upon the uselessness of the ordinary speed formulas, and urged the desirability of having all steamers, if possible, tried progressively. He gave conclusive force to his arguments by exhibiting curves of power and speed for several ships, which showed large departures of the curves given by the standard formulas from the curves which had been deduced from actual trials of the ships. He never afterwards ceased to call attention to the great advantage of the improved system of speed trials; and he soon had the satisfaction of seeing it brought into general use. Mr. Froude said, in 1876, in one of the papers above referred to: "It is to Mr. Denny's honour that, finding the so-called constants [in the speed formulas then in use] were invariably variable and inconstant, he determined of himself to strike out a new line, and find out by trial what is fact, instead of contenting himself with assuming what ought to be the relation between indicated horse-power and speed."

In 1881, Mr. Denny, with the consent of his partners, took the important step of erecting an experimental tank in the shipyard at Dumbarton for the purpose of carrying out independent trials of the resistance of models such as Mr. Froude had long been doing at Torquay. So long before as 1877 he said at a meeting of the Institution of Naval Architects: "The attention of all mercantile naval architects should be called to the fact that all Mr. Froude's experiments bear strongly and directly on our work; and unless we follow them thoroughly and follow them accurately, and with an anxious spirit, we shall not succeed as we ought in taking the lead of those countries interested in shipbuilding." His biographer says that in 1881, when a large extension of the Dumbarton shipyard was commenced, "the erection of an experimental tank became a subject of serious consideration with Mr. William Denny. He had become convinced that the expenditure involved in the construction and maintenance of such a tank would be justified by its utility. The result was that the present Dumbarton tank, the only one either in existence or in contemplation under private control, was devised, constructed, and equipped." The magnitude and difficulty of the work will be understood when it is remembered that the water-space contained in the so-called tank is 300 feet long and 22 feet broad, and the depth of water 9 feet; that the models experimented upon are fashioned out of solid paraffin by mechanism originally devised by Mr. Froude for the purpose; and that the models are towed from end to end of the tank by means of an overhead carriage fitted with delicate apparatus for accurately measuring the speed of the model and the force applied to maintain it at that speed, and for automatically producing a graphic record, in a form suitable for subsequent measurement and calculation, of the results of each experiment. The outlay and thought demanded by such an extensive, complicated, and novel undertaking was very great; but the greatest difficulty of all would be the formation of a staff competent to make it fruitful and successful in results. Mr. Froude was a man of genius, and everyone could not work with his tools. However, Mr. Denny soon organized a staff of skilled assistants who have proved their fitness for the task to which they were put. Prof. Bruce says that "since the tank was opened some twenty thousand experiments have been made on models of ships previously built and tried on the measured mile, or of ships in process of design, or of ideal ships conceived for the purposes of experiment."

Mr. Denny did much to simplify and improve the methods of calculation for determining a ship's stability, and to apply the known science of the subject to the practical work of the designing office. In 1880 he commenced the practice of ascertaining by experiment the position of the centre of gravity of every ship built by his firm; and the data thus obtained for numerous ships were perfected and carefully systematized for guidance in the preparation of new designs. Amsler's mechanical

integrator, and other mechanical devices for reducing the labour of calculations made in a naval architect's office, were extensively used; and the time required for such work was reduced to a small fraction of that formerly expended. The integrator was modified by its inventor at Mr. Denny's suggestion, so as to be better fitted for the special work of stability, and other, calculations; while, on the other hand, the integrator was used so as to enable large simplifications to be effected in the systems of calculation. The manner in which the mechanical integrator was used in Mr. Denny's office to reduce the time and labour involved by laborious calculations, and to effect improvements in the methods of calculation themselves, is well illustrated by one of Mr. Denny's most valuable contributions to the science of naval architecture, which is contained in a paper on "Cross Curves of Stability, their Uses, and a Method of constructing them obviating the Necessity for the Usual Correction for the Differences of the Wedges of Immersion and Emersion."

Mr. Denny, as was his custom throughout, gave a practical direction to his work in connection with the subject of stability, by preparing for each steamer built by his firm general particulars of her technical qualities, "such as dead-weight capability, speed and power, stability," and other matters of importance, for the guidance of her owner and captain.

Mr. Denny was one of the most prominent advocates and pioneers of the recent change from iron to mild steel as the material of a ship's construction. He was the builder of the *Rotomahana*, the first mercantile ocean-going steamer constructed of the new material—a vessel which soon answered objections made to the use of steel by grounding on a rocky bottom and proving its superiority over iron when subjected to the roughest of treatment. Mr. Denny showed, in a paper read before the Iron and Steel Institute in 1881, that the extra cost of steel per ton would be more than counterbalanced by savings effected in the weight of structure, and by the additional weight of cargo that could thus be carried. The truth of this view was soon proved by the commercial results of the use of steel ships. He was always a consistent advocate of the use of steel, and a stout upholder of its merits against all attacks; and he often pointed out with great force and truth that defects arising from faulty design or bad work had been attributed to the material itself. Hence he strongly urged the necessity for more careful study of structural defects, and of what he called the "morbid anatomy of ships."

It is impossible, within the space at our disposal, to deal thoroughly with, or even to notice all of, the many subjects associated with Mr. Denny's name. He did much to improve the structural details of design, and to bring about the introduction of double bottoms into mercantile steamers. He was always an able and close critic of the rules by which Lloyd's surveyors are guided in the survey of ships for classification, and of the manner in which those rules are carried out. He proposed, in 1877, to frame new rules, by which the displacement of a vessel would be the standard for regulating the thickness of the plating and the sizes of the frames and other parts. Mr. Denny's arguments were met with what, at the time, may have been a sufficient answer, viz. that there were no fixed load-lines for ships, and therefore there was no definite amount of displacement. This answer does not now hold good, however, seeing that since the report of the Load-line Committee, in 1885, full means have been in operation for fixing the load-lines, and therefore the displacements, of ships. But there still remains much to be said, on both sides, about Mr. Denny's proposals.

Mr. Denny did some very valuable work as a member of the Load-line Committee, a description of which will be found in Chapter IX. In that Committee; at an interview with the President of the Board of Trade in 1883; in giving evidence before the Royal Commission on Loss of Life at Sea in 1885; and on all other suitable occasions, Mr. Denny advocated a reform of the Marine Department of the Board of Trade, in the direction of forming a Board whose members would have personal knowledge of the subjects dealt with and the interests affected by them, and of strengthening the executive staff of that Department by furnishing it with the best scientific assistance that could be procured.

The cause of technical education never had a stronger supporter than Mr. Denny. He advocated it, and worked in it, at all times and seasons. Everyone engaged in the scientific teaching of naval architecture had his eager encouragement and generous help. The writer owes much to him for practical assistance of every kind in connection with the commencement and carrying on of the work of the Chair of Naval Architecture in Glasgow University. Mr. Denny was always ready to apply the resources of his establishment to the benefit of others who were working in the cause he had at heart. He was an ardent advocate of technical education for all who were entering the shipbuilding profession. His own early training was very thorough, and he qualified himself, as the record of his work proves, to occupy the first rank among naval architects. Yet we find him dissatisfied, and saying in 1883 to one who consulted him as to sending a son to the Royal Naval College, "None of the rest of us [the exception referred to is his brother Mr. Archibald Denny, who now ably fills his place at the works] were at the College, and it will be a lifelong regret to me that I missed its advantages. . . . The work of these schools [of naval architecture] is the leaven which is slowly but profoundly inspiring and changing the character of our profession." The practical efforts made by Mr. Denny himself among his own people to improve their technical training are best described in his own words. In 1883, he said:—

"Our attempts at technical education in our shipyard and engine-works consist of the following:—

"(*a*) Rules as to the admission, by examination, of apprentices and others into the shipyard offices.

"(*b*) The same for our engine-works.

"(*c*) Rules to the Awards Committee to guide them in rewarding the workmen for inventions or improvements.

"A similar scheme of awards has been begun in our engine-works.

"From these papers and the private information given to you as to the awards made, you will observe that our attempts to stimulate the intelligence of our *employés* have developed in two forms, corresponding to the main divisions of these *employés*. First, by examination we have tried to secure a supply of apprentices and others for our offices elected by ability and steadiness, and with some knowledge suitable for the careers before them,

Second, we attempt by rewards to stimulate the minds of our workmen directly to invention and to a continual criticism of the methods of work, tools, and machines employed by them. We have not tried yet to induce them to attend technical classes, but a few of them do attend such classes in the town, conducted under the control of the Science and Art Department.

"All our draughtsmen attend such classes, and in addition have from us the use of our offices, with paper, &c., free, also of a very complete library of works on naval architecture and cognate subjects, every evening excepting Saturday and Sunday."

Mr. Ward, the managing partner of the firm, reported, in 1887, that, since the introduction, seven years before, of the system of awards to workmen for inventions and improvements, "claims have been considered valuable and worthy of award to the number of 196, while rather more than three times that number have been considered altogether."

Want of space prevents our saying more respecting the subject of this memoir, though much more might be said with advantage. The early termination of Mr. Denny's career is an irreparable loss to his profession and to the cause of scientific progress in ship construction. The last professional distinction conferred upon him was that of being elected President of the Institution of Engineers and Shipbuilders in Scotland; but he did not live to deliver his Presidential address. This circumstance in connection with his death is similar to what happened in the case of a celebrated predecessor in that office, also a Clyde shipbuilder. We refer to Mr. John Elder, who died in the prime of life almost immediately after the members of the Institution elected him as their President in 1869. FRANCIS ELGAR.

MEMORY.

Memory: its Logical Relations and Cultivation. By F. W. Edridge-Green, M.B., B.S. Durham. (London: Baillière, Tindall, and Cox, 1888.)

THE title of this book is somewhat misleading. "Memory: its physiological" or "organic conditions," would be more pertinent, for "logical relations" suggest a treatment of mental association more allied to that offered, for instance, by Dr. Bradley in his "Principles of Logic." This will probably appear a trifling remark to the author, niceties of terminology seemingly being of small importance in his eyes. Throughout his work the writer lightly passes from the corporeal to the mental sphere with a serene indifference to the needs of clear conception.

The author's stand-point may be understood from the following paragraphs of the introduction:—

"What is memory? It is the process by means of which impressions of the external world and ideas are retained for use on future occasions. . . .

"Memory must be clearly distinguished from remembrance and recollection. Recollection is the power of voluntarily recalling impressions. Remembrance is the term applied when the process is involuntary. Memory is the innate power to have an impression recalled if a proper stimulus be applied. . . .

"All the above appears at first sight to be strongly against the view that memory is a definite faculty occupying a limited portion of the brain. But in the following pages I shall endeavour to prove that memory *is* a definite faculty, and has its seat in the basal ganglion of the brain, separate from, but associated with, all the other faculties of the mind."

Mr. Edridge-Green evidently does not fear the reproach of heresy, for there is hardly a sentence of the foregoing that would not be condemned by the authorities of the day. Whether memory be defined as "the process by means of which impressions and ideas are retained," or "the innate power to have an impression recalled" (we leave it to the author to reconcile his own language), —to mark it off from "remembrance and recollection" would, by most psychologists, be regarded as making a distinction without a difference. And, further, to maintain that "memory is a definite faculty occupying a limited portion of the brain," with "its seat in the basal ganglion," undoubtedly is a proof of independent opinion, if not of scientific discretion.

We are treated in chapters v. and vi. to an account, at some length, of "the faculties of the mind," as well as —although we had been told that memory is *a* definite faculty occupying a limited portion of the brain—of "the special memories" appertaining to the same. The faculties turn out to be thirty-seven, the number being five short of those alleged in "the phrenological system," the items of which are in part rechristened, and also rearranged. Regarded as conformity to popular description, there may be no great harm in all this; but something more than language is at fault in the statement that "the mind is made up of a number of faculties, each of which responds to certain impressions, and influences the mind as a whole to seek after these impressions, and to avoid their negatives." Indeed, many of the author's perplexities, and much of the reader's difficulty in comprehending him, are clearly traceable to the adoption of this somewhat antiquated and crude way of regarding the mental constitution. The topic, however, must not detain us, and we proceed to consider the author's refutation of "the hypothesis that the perception and memory of any impression occupy the same portion of the brain."

Eight reasons are apparently offered. No. 1 had perhaps best be given in the author's own words:—

"They [*i.e.* perception and memory] are totally distinct functions; thus, the eye receives the impression in the first place, but no one supposes for an instant that the eye is the seat of the memory of impressions of sight. . . . Why should the brain, having manufactured ideas, &c., remember them? The cerebral hemispheres bear exactly the same relation to the basal ganglia as the external senses do, and there is no evidence to support the theory that the cerebral hemispheres are the seat of memory."

The reasoning apparently is: the cerebral hemispheres (which possess the property of *manufacturing ideas*) stand "exactly in the same relation to the basal ganglia as the external senses." Now it is admitted that the eye, or external sense, remembers nothing, therefore neither can the cerebral hemispheres. Is this meant for reasoning, or mere dogmatism? No one who has not a theory to support would press the analogy of the eye and the cerebral hemispheres; resting as it does on nothing better than a vague resemblance of the minute structure of retina and cortex; rather, if analogy is to count for anything, it is the "basal ganglia" that should be likened to

the sense-organ, for their part, if not whole, function in the perceptive act is mediatorial.

Argument 2: "The view that the memory of an impression occupies a part of the brain distinct from the perception is simpler and more consistent than superadding the function of memory to that of some of the faculties. Thus, why should the instinct to acquire and its special memory occupy different portions of the brain, whilst the perception of a form and its memory occupy the same portion?" But who but our author alleges that they do occupy different portions?

Most of the other arguments turn upon the implications of the faculty-hypothesis, and lose whatever force they seem to possess by the abandonment of that mode of conceiving mental phenomena. Thus, No. 5: "The absolute impossibility of understanding how an impression could be split up, so that each faculty might take its share of an impression." Material separation of faculty-areas apart, one does not readily see the point of this difficulty.

Our author says: "I will take for illustration the faculty of colour, as being the *very simplest* possible; but by no stress of imagination can I conceive how an impression of colour can exist, apart from the impression itself, to be of any definite use in remembrance." The reader's imagination will very likely be as much taxed as the writer's; indeed, he will probably vainly try to imagine what the author is exerting himself to imagine. After much straining, I seem to myself to seize the intended meaning in the following rendering. The mind being regarded as an aggregate of distinct faculties, the *matter* of any impression will be simultaneously apprehended by several. Now the energy of a faculty is a function of the hemispheres. But that which is common to several faculties cannot be the exclusive property of any one. In remembering, the perceiving faculty is dormant; therefore, in remembering, some other region of the brain must be excited.—But how if the initial assumption be denied, and memory of the perception be no other than the perception *minus* the outlook? Is this not sufficiently proved by the fact that there can be no memory where there never was presentation; and that remembered presentation can, in certain circumstances, attain the intensity of original presentation?

But if mental revival be not the subjective concomitant of renewed cerebral agitation of a definite kind, how ought we to conceive the state of the case?

Thus: "all sensory impressions, whether elaborated by the faculties of the mind situate in the cerebral hemispheres or by the sensory nerves, are permanently stored up in the optic thalami, and constitute the sensory memory"—the equivalent of psychical retentiveness. Then these stored-up impressions find a way out of their hiding-places through one of two opportunities. Either when some similar impression passes "through the sensory memory centre on its way up to the mind" (= remembrance); or "through the intervention of the mind" (=recollection). The writer shows no signs of having thought out all that his descriptions imply. As for the relegation of the function of memory to the basal ganglion, nothing deserving the name of evidence is forthcoming.

In his treatment of memory in the strictly subjective aspect, Mr. Edridge-Green shows to more advantage, although a certain want of lucidity here as elsewhere forms a serious defect. He instances three laws of remembrance, which must be given in his own words:—

First Law.—"All impressions tend to revive those of a similar character previously received; but an impression in the sensory memory will not be brought before the consciousness if its psychical intensity does not reach a certain definite standard. This psychical intensity is attained by the association of impressions representing similar members of a psycho-physical series contiguously combined in a similar manner."

The law seems to amount to this: As the points of similarity in two impressions, one old and one new, increase, is the chance of recognition increased. So interpreted, it is the equivalent of what is frequently called by psychologists the law of Similarity. The law as stated by our author involves, however, his third law, or that familiarly known as the law of Contiguity.

The similarity referred to in the first law detached from contiguous association is made the subject of the second law of remembrance, which runs—

"When an impression is received similar to one received previously, unless the previous impression be revived at the same time, both impressions will remain separate; whereas if the previous impression be brought before the consciousness and recognized as similar, an association of the two impressions will take place."

The implication of this law is that the similarity of impressions alone does not suffice for revival. Over and above the resemblance of the impressions themselves there must be a perception of the resemblance. One would have thought, indeed, that this went without saying. Physical similarity or even identity is not conscious perception of resemblance. The students who did not recognize the leaf of a plane-tree, although they had been staring at it every day of their lives, had never had in the psychological sense an "impression" of the plane-leaf. The image on the retina preceded no mental image; and when their attention was called to the plane-leaf, they may be said to have then *seen* it for the first time. But having cognized it once, they cognized it always, according to a well-known dictum that cognition and re-cognition are one and the same.

This second law is no pure law of remembrance, then, but a fundamental condition of knowing.

Third Law.—"The revival of a component of an impression tends to the revival of the remaining components, and the revival of any impression tends to the revival of other impressions received about the same time; but unless these reach the necessary standard of psychical intensity, they will not be brought before the consciousness."

This is a not unhappy wording of the great law of mental association, the "law of contiguity."

As a statement of principles, whether physiological or psychological, I cannot hold this book on the mysterious subject of Memory to be a valuable contribution to scientific literature. There is evidence throughout of first-hand observation and of genuine effort to acquire an original comprehension of both physical and psychical phenomena, but the materials are ill-arranged, and the theorizing crude or mistaken. It might be well if the author, before pursuing his inquiries in this field, made

himself more acquainted with the present condition of physiological and psychological research.

The most satisfactory part of the book is the concluding section, entitled "The Cultivation of Memory," wherein some excellent practical advice is given with regard to methods of acquisition and study, the adoption of which would save much commonly wasted time and labour.

W. C. COUPLAND.

THE SPECIES OF FICUS OF THE INDO-MALAYAN ARCHIPELAGO.

The Species of Ficus of the Indo-Malayan and Chinese Countries. Part II. Synœcia, Sycidium, Covellia, Eusyce, and Neomorphe. By George King, M.B., F.R.S., &c. *Annals of the Royal Botanic Garden*, Vol. I. Part 2, pp 67–185, tt. 87–225. (Calcutta: Printed at the Secretariat Press. London: L. Reeve and Co. 1888.)

THE first part of this excellent illustrated monograph of a very difficult genus was reviewed in NATURE, vol. xxxvi. p. 242, where some details are given of the classification adopted by Dr. King. The present part completes the volume; but it is intimated that a supplement is to follow, dealing with the new species recently collected by Mr. H. O. Forbes in New Guinea, and containing an account of the fertilization of *Ficus Roxburghii*, by Dr. D. D. Cunningham. A photograph of a tree in fruit of this remarkable species forms the frontispiece to the volume. It is one of those species which bear the fruit on the trunk; and in this particular tree the fruit is heaped up around the base of the trunk in such profusion as to suggest the idea of its having been placed there. Several species of the section *Covellia* exhibit this peculiarity; and some even go farther and bury their fruit in the ground, where it ripens, like the earth-nut *Arachis hypogæa*. *Ficus conglobata*, King, and *F. hypogæa*, King, belong to this group. The former bears enormous clusters of figs which are wholly or partially buried in the soil; and of the latter, Mr. H. O. Forbes, who collected it in Sumatra, at an altitude of 5000 feet, says "the fig-bearing branches issue from the stem very near the ground, and at once become sub-terrestrial, producing figs either entirely or partially buried. These figs when very young are devoid of colour in the upper half, but pinkish in the lower half. When a little older they become reddish-pink all over, and when mature they are of a greenish-grey colour."

Another highly curious species is *Ficus Minahassæ*, Miquel, a native of the province of Minahassæ in the Celebes. Miquel truly says this is "Omnium Ficuum maxime singularis." The figs (receptacles) are only from one-tenth to one-fifteenth of an inch in diameter, crowded together in little balls, about an inch in diameter, and borne on long slender pendulous leafless branches.

Ficus hispida, Linnæus, is one of the commonest species throughout tropical Asia, and extends to North Australia and Hong Kong. It is also very variable, the variability being in a great measure due to the different situations in which it grows. This species bears the receptacles (figs) in pairs in the axils of the leaves, or in clusters on the trunk, and sometimes they occur in both positions on the same tree at the same time. The fruit from the trunk sometimes burrows in the ground, and Roxburgh seems to have been the first to record the phenomenon. On the sandy lands near the sea on the coast of the Tanjore country, he states, the whole raceme and fruit are often entirely underground. Whether it was for this reason or not that this variety received the name of *F. Dæmonum* is not mentioned, but Vahl gave this name to specimens collected by Kœnig.

With regard to the execution of the second part of Dr. King's monograph, more especially the lithographs, the work of native artists, there is, if anything, an improvement on the first part; and the dissections are throughout on the same plate as the species to which they refer (instead of on separate plates as in the first part), which is much more convenient. The total number of species described is 207, many of them new; though, on the other hand, Dr. King has reduced a very large number of species founded by other authors, especially by Miquel, on fragmentary herbarium specimens. In several instances two species were founded on the different sexes of the same species, based upon differences in the shape and other characters of the receptacle. On this point it may be mentioned that Count Solms's and Fritz Müller's investigations of the sexual relations of the fig and caprifig, and the investigation of other species by the former, had led botanists to expect greater diversities in the male and female receptacles than would appear from Dr. King's researches to exist. He says:—"In by far the majority of cases these two kinds of receptacle [*i.e.* male and female], so physiologically distinct, are undistinguishable by external characters, and they are borne by the same individual plant. They look exactly alike until one opens and examines their contents. The most notorious of the few exceptions to this rule is the common eatable fig (*Ficus Carica*)." These differences have been fully discussed from time to time in NATURE. What is more surprising than this sexual similarity is that in certain species having dimorphic receptacles, the dimorphism Dr. King finds bears no relation to the separation of the sexes. For example, *Ficus trachycarpa*, Miquel, having spherical verrucose receptacles, Dr. King considers to be the same species as *F. clavata*, Wallich, which has larger ovate or obovate receptacles; and he says:—"There is no absolute sexual relation between the external form and the contents of the two kinds of receptacle which occur in this species; but, so far as I have observed, the large obovoid clavate receptacles invariably contain male and gall-flowers, and the males are not confined to a zone near the mouth, but are to be found on all parts of the interior of the receptacle. Of the small subglobular receptacles, however, some are exclusively filled with fertile female flowers, while others (like the large clavate receptacles) contain males and gall-flowers mixed together." One would almost suspect an error in the identification of these two forms as one species, though in foliage they are absolutely alike.

But, apart from all physiological considerations, it is a matter for congratulation that this useful work has been completed, and Dr. King has earned the thanks of all his fellow-botanists.

W. B. H.

OUR BOOK SHELF.

Questions and Examples on Elementary Experimental Physics. By Benjamin Lœwy. (London: Macmillan and Co., 1888.)

THIS book contains some 470 questions and examples in elementary physics, selected from the various papers set by the author for the examinations of the College of Preceptors. The questions are arranged under the four sections, sound, light, heat, and electricity and magnetism, and are further subdivided in each section into groups of five or six, with the suggestion that each group should form the subject of an ordinary school lesson. Problems involving a knowledge of mathematics beyond elementary arithmetic and geometry are avoided; in other respects the general standard of the questions is about that of the advanced stage of the Science and Art Department's examinations. The questions are well selected, and free from ambiguity or repetition. We notice under Heat, ix., 1, the question: "In the process of graduating a thermometer, why must the freezing-point be determined before the boiling-point?" This is the order of operations as usually given in the text-books, but it has been shown in the elaborate report of the Bureau des Poids et Mesures that the interval between the freezing and boiling points is most constant when the freezing-point is determined as soon as possible *after* the boiling-point.

We can recommend this little book to the attention of those teachers who have to prepare pupils for the public examinations in elementary physics. For success in such examinations it is not sufficient that the pupils should possess the requisite amount of knowledge: they must also acquire the power to express their knowledge clearly and concisely on paper, and such power it is one of the functions of such a book as this to impart.

H. H. H.

The Unknown Horn of Africa. By F. L. James, F.R.G.S. (London: G. Philip and Son, 1888.)

THIS is an extremely interesting record of an exploration from Berbera to the Leopard River, undertaken about four years ago. Various attempts had been made, before Mr. James's journey, to penetrate to the interior of Somali Land, but without success. Mr. James and his companions, more fortunate, or more skilful, than their predecessors, contrived to push their way to the goal for which they started; and the result is that the present volume is accompanied by a map embodying much new information regarding a district of considerable extent and importance. Some of the difficulties encountered by the party were formidable, but courage and perseverance enabled the travellers to overcome every obstacle. Mr. James has much to tell us about the flora and fauna of the country, as well as about its physical features; and he has many lively and instructive passages describing his relations with the natives, whose peculiarities he seems to have thoroughly understood. The story is itself so interesting, and is told in so bright and pleasant a style, that the book ought to be one of the most popular of recent works of travel. It is illustrated by a number of excellent coloured plates, and by various effective pictures, composed from photographs of natives and native scenery taken on the spot.

Seas and Skies in Many Latitudes. By the Hon. Ralph Abercromby. (London: Edward Stanford, 1888.)

THIS is not an ordinary book of travels. It has been written mainly for the purpose of calling attention to such phenomena of the sky and weather as Mr. Abercromby has observed in various parts of the world. The opening chapter describes the author's experiences in Canada and the United States in the year 1865. Then he gives an account of a voyage round the world, beginning with what he saw in Egypt, and passing on to descriptions relating to Australia, New Caledonia, Fiji, New Zealand, Cape Horn, and Rio Janeiro. Mr. Abercromby next takes his readers within the Arctic Circle, and afterwards he tells of a long journey, in the course of which he was at the Cape of Good Hope, Mauritius, Ceylon, the Himalayas, Borneo, Manilla, San Francisco, and Washington. He by no means confines his narrative to matters specially attractive to meteorologists. He takes interest in many different classes of subjects, and has something more or less memorable to record about almost all the places he has visited. It is, however, meteorology that he keeps chiefly in view, and we need scarcely say that on this subject, which he has so long and carefully studied, his book is always fresh and instructive. The value of the work is increased by good maps and illustrations.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Alpine Haze.

WITH the caution of a true man of science, Prof. Tyndall has given this name to a phenomenon observed by him in the Alps. Does not W. Clement Ley beg the question by calling it "dust-haze"? I should translate his *nebula arida* by "dry haze."

Two hundred years ago, Ludolf gave the best definition of *qobar* by translating it: "*opacitas aeris qualis solet esse tempore fervidissimæ æstatis.*"

In my last letter I quoted several names of it, in order to show that the vulgar eye has long distinguished this phenomenon. I have since learnt that, in the Basque dialect of Gipuzkoa, its proper name is *bisuntsa*, but that seafarers call it *lur-autsa, i.e.* "earth-haze," *lañoa*, meaning common fog. The Ethiopic name, *qobar*, comes from *qabbara*, a root extant also in Hebrew and Arabic, and meaning *to bury*. *Qobar* hides the landscape, and conceals stars of the third magnitude, even in the zenith. Gasparin observed it on Mount Ventouk, where he crossed a thick cloud which made no impression on his hygrometer. Humboldt, viewing *qobar* in Peru, says, "Quelle est cette vapeur qui est visible et qui ne mouille pas?" but leaves his question unanswered.

While travelling in Spain, Willkomm remarked *qobar* at a distance of 3 or 4 miles, yet, on reaching the actual spot, he saw nothing. He clearly distinguished it from the *landrauch* ascribed to smoke caused by turf burning in Westphalia, and thinks, like Spaniards, that *callina* increases with solar heat. Several German authors have spoken of this phenomenon as smoke, but Egen is the only one who has followed it up from place to place through an extent of 200 kilometres, and rendered it probable that it then covered a space of more than a thousand square myriametres. It seems, however, that particles of smoke should attract moisture, if there were any in the air, and then form real clouds or otherwise fall to the ground by increase of weight.

Bravais saw *qobar* on the Faulhorn, when his hygrometer was at 51, air saturated with moisture marking 100. In Ethiopia, where I have observed it so low as 20, the hygrometer's mean reading was 41 when *qobar* was conspicuous. Above 72 it disappeared. These figures apply to the place of observation. Conclusions can be safely drawn only when the air's moisture shall have been measured in several places along the line of sight up to the spot where *qobar* prevails, or, better still, in that spot itself when recognized from a distance.

Since I published my first account of *qobar*, Martins, who observed it in Auvergne, Switzerland, and from Mount Canigou, is the only author who has specially described it. He says that the Swiss call it *hâle*, and that he saw none of it in Lapland. In spite of Kaemtz's remark that, moisture being the essence of all fogs, a "dry fog" is an expression not less un-

meaning than a "triangular square," Martins divides his "*brouillards secs*" into four classes, viz. volcanic ashes as seen in the year 1783; smoke from turf or stubble fires; *callina* or *qobar;* and a fourth kind established on negative evidence which seems untrustworthy.

W. Clement Ley has described quite well the hues of *qobar*. It is light buff when near or slight. Otherwise, its colour is a lurid gray verging to blackness. Whatever may be its connection with cumuli in England, I could detect nothing of the sort in Ethiopia, where I have watched *qobar* for whole weeks without any ensuing rain or even cloud.

Four years ago the French transit of Venus expeditions agreed to investigate the amount of carbonic acid gas in the air of their several stations. Mine was in Hayti, where *qobar* was rife, and while observing for many consecutive hours the passage of air through caustic potash in prepared tubes, I regretted their not being made to receive plugs of loose cotton in order to collect smoke, dust, or microbes. All the tubes having been subsequently tested in Paris by Prof. Müntz, he obtained the unexpected result that air contains more carbonic acid in the southern hemisphere than on the north of the equator. Those tubes inclosed also fragments of pumice-stone previously steeped in sulphuric acid in order to collect moisture. With a little care and trouble next summer in a spot of Southern Europe where *qobar* abounds, meteorologists might soon get an insight into its true nature.

January 3. ANTOINE D'ABBADIE.

SEVERAL communications have appeared in NATURE on the subject of atmospheric haze. It would be interesting to know whether the writers consider the haze which they have described as identical in substance with that which I would call *ordinary* atmospheric haze. The haze of these writers is a haze taking the visible form of layers or bands. The haze to which I refer has under ordinary circumstances no visible form at all. We are conscious of its presence by its effect in diminishing the transparency of the air. Everyone knows that, quite apart from fog, or smoke, or dust, or low cloud, or falling rain, the transparency of the air varies very greatly at different times. In our climate there is nearly always more or less of atmospheric haze, the rare exceptions proving the rule; and the haze may be so dense as to render terrestrial objects invisible at a distance of a very few miles. Celestial objects may also be obscured by the same cause. Not to speak of the varying brightness and varying colour of the sun at sunset (in the production of which effects another cause may co-operate), there are occasions on which the sun long before sunset is shorn of his beams through the intervention of a low general haze, the hygrometric conditions at the time being such as to preclude the idea of fog, to which indeed the haze referred to bears little resemblance.

On July 24, 1868, I witnessed from the summit of Snowdon a curious effect of this diffused haze. The day was cloudless. Overhead the sky was clear and blue, but at lower altitudes it was hazy, and the haze gradually thickened towards the horizon, where it terminated in an opaque brown ring, which encircled the mountain and shut out from view all objects beyond a distance of about 15 miles.

The nature of atmospheric haze has not, I think, hitherto been satisfactorily elucidated, and it is much to be desired that advantage should be taken of some occasion when the haze is exceptionally dense, for the application of the various methods of research which modern science has rendered possible.

Clifton, December 25, 1888. GEORGE F. BURDER.

On the Use of the Words "Mass" and "Inertia"—a Suggestion.

As a teacher of dynamics to Engineer Students, I followed with interest the discussions in NATURE, as to the use of dynamical terms, that have taken place within the last two years, and have recently re-read the whole correspondence with care. Two points seem to me to have been not quite sufficiently brought out.

(1) Physicists and teachers of dynamics, however careful they may desire to be, use the word "mass" in two senses: (1) in the old, non-scientific, (Johnsonian) sense of a "lump of matter," and (2) in the precise scientific sense of the "inertia" of a lump of matter. Indeed, I suppose that no scientific man would hesitate to speak of "the inertia of a mass of matter."

The phrase "attracting mass" is universal among scientific men, when attracting "lump" would do just as well. Thus, in Prof. MacGregor's very carefully written "Kinematics and Dynamics," we find, in Art. 290, "mass" carefully defined (in the sense of inertia) as the value of a certain ratio, and in the next article the use of the word in the sense of quantity of matter is deprecated; yet, in Art. 355, we have "attracting mass" where attracting "inertia" would not do, followed, a few lines further on, by "a particle of unit mass" where "unit inertia" would serve as well.

It is this double use of the word that, I think, sometimes escapes Engineers.

Each of the words "mass" and "weight" is used in two senses, one of which is common to both, but the other not. The fact confirms very strikingly Prof. Greenhill's contention that the scientific man is unwise to attempt to limit for his own purposes the signification of a word already well established in the language. For it shows that he cannot even keep straight himself. I think myself that the scientific man ought to back out with as much grace and celerity as may be, and determine for the future to say "inertia" when he means "inertia," and to use for its numerical representation the symbol "i" (or perhaps "s"—sluggishness) rather than the symbol "m." The symbol "I" might still be used for *moment of inertia*. Such an expression as a "mass of 20 pounds" would still mean exactly what it does at present, and nothing already written would be affected by the change.

(2) The second point that I have to mention is purely a question of procedure in teaching.

The whole subject of dynamics might well be termed the study of the inertia (the "sluggishness") of matter. This is the one new property whose existence, signification, and measurement has to be brought home to the student. Now, I would urge that it does not seem reasonable to ask the student simultaneously to comprehend a new property of matter and to alter his unit of force by defining it with reference to the new property. Do what we will, our students before they begin to learn dynamics will be familiar with the notion of "force" as a "push" or a "pull," and measured in terms of "pounds" and "ounces."

I think it would be far the best plan to define the British unit of force as the weight *in London* of the standard pound lump, and the unit of inertia as that of the mass or lump on which this force generates the unit acceleration of 1 foot-per-second per second.

Thus the unit of inertia would be that of 32·1912 standard pounds, the number 32·1912 being, for brevity, throughout the teaching, written "g."

This would be to adopt with careful definition, by which it is rendered perfectly precise, the Engineers' unit of inertia for purposes of instruction in dynamics. It means empoying a *force-time-length* system of units instead of an *inertia-time-length* system.

Such a system would be in harmony with the order of our experiences and of our ideas as we grow in intellectual stature, and with the history of human thought as written in our language, and it is unwise to wage war with our own past even under the encouraging leadership of your correspondent "P. G. T."

Perhaps I may be allowed here to deprecate the somewhat misleading effort now being made by some chemists and physicists to substitute the word "mass" for "weight" where no question of inertia is involved or dreamt of, as, for instance, in the definition of specific heat, by reference to equal masses, instead of equal weights, as if the idea of quantity of matter had not been attained quite independently of the conception of inertia, and were not in the case in question always determined by weighing. A. M. WORTHINGTON.

Royal Naval Engineer College, Devonport,
December 30, 1888.

Eight True Ribs in Man.

IN the number of NATURE which appeared on November 1, 1888, there is a notice to the effect that "at one of the meetings of the Anatomical Society, during the session of the Medical Congress in Washington, Dr. Lamb, of the United States Army Medical Museum, spoke briefly of a singular phenomenon he had observed in his examination of human breast-bones. It was the occurrence, in a number of specimens, of an eighth rib,

the cartilage that is usually found below the seventh rib being fully developed into a rib." This description is somewhat ambiguous, but I presume it refers to the occasional elongation of the eighth costal cartilage in man, and its direct articulation with the sternum. At the time when I read this notice I was organizing a system of "collective investigation" in my class of practical anatomy, in Trinity College, Dublin, and I asked Mr. O. L. Robinson, one of my assistant demonstrators, to undertake the investigation of this point. During the last two months he has examined thirty subjects, and he has found the eighth costal cartilage united to the sternum in no less than five of these. In four subjects (two males and two females) the eighth cartilage of the right side alone showed this condition; in the remaining case (a male) the eighth cartilage on each side reached the breast-bone and articulated with its fellow in front of the upper part of the ziphi-sternum. The anomaly is therefore one of some frequency, seeing that it has been noted by Mr. Robinson in about 17 per cent. of the subjects which he has examined. I may mention that all the specimens are now in my possession.

But my object in making this communication is not so much to record the results obtained by Mr. Robinson, seeing that these will be more fully dealt with elsewhere, as to call attention to a remarkable statement which is made by NATURE on the authority of *Science*. It runs as follows:—"Dr. Lamb has made a thorough search of anatomical literature for references to this peculiarity. In the English books there is only a single incidental reference to it, and in that case the author does not say that he has ever seen a specimen. In German books there are two references. one of them being the one mentioned by the English authority." Certainly this is not my experience of the literature on this subject. There is hardly a German text-book of importance in which the anomaly is not referred to.[1] Thus Gegenbaur, Aeby, Luschka, and Henle, all mention it, and the two last enter into the question at some length. Henle likewise quotes the observations which have been made upon this point by Hyrtl and Prof. Oehl of Pavia. It is true that our own text-books are for the most part silent on the subject, but Prof. Humphry in his classical work on the human skeleton, p. 323, remarks: "In a specimen in the Cambridge Museum, which measures seven inches, there are eight cartilages of ribs separately united to the sternum." This is not the description of a man who has never seen such a specimen.

It is interesting to note that, of the ten cases recorded by Dr. Lamb, nine occurred in Negroes and one in an Indian. Luschka, referring to the assertion that the anomaly is more frequently observed in black races, says: "Im Verlaufe weiterer Nachforschungen hat es sich jedoch herausgestellt, dass bei den Negern nicht häufiger als bei anderen Menschenstämmen und immerhin nur in Ausnahmsfällen acht Rippenpaare an das Brustbein angeheftet sind" ("Die Anatomie der Brust," 1863, p. 119).

Another feature of interest in connection with this anomaly is centred in the fact that in the lower apes, and also in the chimpanzee, it is the typical condition. As a rule, they present eight true ribs on each side. The orang, however, resembles man in this respect, and normally possesses only seven true ribs. Curiously enough, the transition stage between man and the orang on the one hand, and the chimpanzee on the other, is to be found in the gibbon. In this ape, so far as my experience goes, the cartilage of the eighth rib, although it is long and rests by its tip against the ziphi-sternum, does not articulate with the sternum. A condition similar to this is occasionally seen in man. D. J. CUNNINGHAM.

Trinity College, Dublin, January 2.

"The Cremation of the Dead."

IN your excellent article on the above subject (p. 219), it is stated that a provision contained in the will of a testator directing the cremation of his remains has no legal effect. This is no doubt correct, for, although the law permits a man to dispose of his property by will, it does not permit him to dispose of his own corpse.

This legal difficulty may, however, be surmounted by an indirect method. Most testators bequeath legacies to their executors, and also to their nearest relatives; and the legacies bequeathed to the latter are not unfrequently of considerable value, even when the testator is a man of only moderate means. If, therefore, each of the legacies are made conditional upon the legatee taking, or concurring in taking, the necessary steps to procure the cremation of the testator's remains, the wishes of the latter would in the majority of cases be carried into effect; since any attempt on the part of a legatee to interpose any obstacle would involve the forfeiture of his legacy. A. B. BASSET.

Conservative Club, S.W., January 6.

"Degradation" of Energy.

IT may perhaps have occurred to others besides myself that the term "degradation"—as applied to the transmutation, for instance, of mechanical energy into heat energy—is a rather stronger one than our present knowledge warrants us in using: that it casts, in fact, an unmerited slur on the character of that eminently respectable concept, energy. We seem hardly justified in supposing that any *intrinsic* deterioration of the energy takes place in such transmutations as the above.

Might not "depreciation" be a rather preferable expression? This would imply nothing more than a lowering in the value of energy in relation to the particular needs and mere agencies of man, and not any absolute change in its character for the worse.

Similarly, money securities are said to be "depreciated" in a particular market, while they may not be at all lessened in absolute value. H. G. MADAN.

Eton College.

Hares Swimming.

IN *Chatterbox* of May 12, 1879, published by Wells Gardner, Paternoster Buildings, is an account by J. G. Fennell of several instances in which he has seen hares swim across both fresh and salt waters. OCTS. DEACON.

Loughton, Essex, January 5.

THE RECENT SOLAR ECLIPSE.

WITHIN the next few days we may expect detailed news of the various parties organized to observe the eclipse of January 1. In the meantime, the following telegram from Mr. Pickering, chief of the Harvard Eclipse Expedition, who was at Willow, California, will be read with interest:—

"The sky was clear during the whole of totality. The corona was larger and more irregularly shaped than usual, exhibiting great detail in its filaments. Three of the geometric contacts were observed. The duration of totality was 118 seconds, or three seconds longer than had been predicted.

"Capital drawings were obtained of the whole corona. Eight negatives were obtained with a 13-inch refracting telescope, and six with an 8-inch telescope, and seven photometric observations were made of the corona's light. The drawings show the corona extending outwards from the sun for two of its diameters—that is, 2,000,000 miles in both directions. The corona somewhat resembled that of the eclipse in July 1878."

Another account of the doings of Prof. Pickering's party states as follows:—

"During yesterday's eclipse of the sun twenty-five negatives were taken at Willow, California, to measure the brightness of the corona and its surroundings. Five of these were obtained to search for intra-Mercurial planets, and twenty to study the spectrum of the corona in order to determine its composition. These negatives will reach from the yellow rays to the extreme ultra-violet.

"The general illumination during the period of totality was found to be lighter than during the eclipses of 1878 and 1886. The corona was similar to those of 1868 and 1878, but showed much more detail than the latter, and was exceptionally fine, extending usually on one side to two solar diameters. A striking characteristic was two forked wings of light. The polar rays were well defined and con-

[1] It is not referred to by Krause, Hermann Meyer, or Pansch, but in these books, as in our English text-books, the omission is evidently due to want of space and not to want of knowledge.

siderably shorter. At Cloverdale, the eclipse was observed with great accuracy, but shortly before totality some cirrus clouds passed over, all tinged with the most brilliant colours of the rainbow.

"Venus appeared during the early stages of the eclipse, while Mercury and the other planets were plainly in view during every phase that was photographed.

"At Willow, the temperature dropped 7°, but the fluctuations of the barometer were quite imperceptible. The velocity of the wind diminished at first, but afterwards increased."

Prof. Todd secured a number of fine photographs of the corona, showing, according to Reuter's telegram, rays extending 10° or 12° from the sun.

At Winnemucca, the United States Signal Service observers made drawings of the streamers of the corona, and also took successful photographs. They saw the edge of the moon projected against the corona for some time after the total phase had passed.

At Lick Observatory, the eclipse was successfully observed, and a number of photographs were taken.

At Norman, California, the fourth contact was observed, but the first was lost in clouds. The moon's limb was not seen projected on the corona either after or before totality, although careful search was made. The telescope was used for making drawings of the corona adjacent to the sun's poles, and the sketches show very complex filaments. The negatives taken are excellent, and show the corona very similar to that seen in 1878. Long streamers were readily traced through 4°.

The party of observation at Bartlett Springs report that the corona was beautifully distinct, and that they saw remarkable changes in the length of the coronal lines. They obtained nine photographs of all contacts, studied the structure of the inner corona, and made measures of light intensity during totality.

Four long streamers were seen proceeding from the prominences, and the chromosphere was strong for a full quadrant distance of the west side of the sun. The northern and southern limbs of the sun showed a great number of fine radiating filaments.

At Chicago, a beautiful view of the corona was obtained. Two long streamers pointed nearly west, and two shorter ones were almost opposite. At the beginning of totality intense red flames burst out on the sun's western side, covering a space of 90°. The inner corona presented a beautiful spectacle in the telescope. Its radiating filamentary structure, with both curved and straight lines, was distinctly seen.

At Healdsburg, although only nineteen-twentieths of the sun's surface were obscured, Venus, Mars, Jupiter, Mercury, and the principal fixed stars were visible. The corona also appeared with long rays of light parallel to the sun's equator.

Mr. Swift, Director of the Warner Observatory, stationed at Nelson, California, reports that, as far as it afforded an opportune search for an intra-Mercurial planet, the eclipse was a failure, owing to clouds and haze.

At Anaheim, no photographs were secured, but it is claimed that an intra-Mercurial planet was seen during the period of greatest obscuration.

At Winnemucca, Nevada, one observer discovered a comet near the sun. No appreciable change of temperature was noticed at this station. Accurate observations were also made of the shadow bands. The corona was similar in general appearance to that of 1878. The streamers extended to a distance of from three to four diameters, and the red protuberances were strongly marked.

At Grass Valley, during the period of totality, the stars and large planets were seen with the naked eye, and the corona and protuberances offered a grand spectacle. The thermometer fell 7° between the moment of first contact and totality. At Virginia City, Nevada Territory, the thermometer fell 10° during the progress of the eclipse.

At Blackfoot, Idaho, all four contacts were observed. A short time before totality the moon's limb was seen projected against the corona. The mercury fell 13°.

From the above accounts it is quite clear that new information touching many important points has been secured. This is most fortunate, for the eclipse occurred at a well-marked minimum of solar spots; indeed, it was as marked as that of 1878, when again the eclipse swept over the American continent and was most fully observed.

There seems no doubt that the expansion of the sun's surroundings in the plane of its equator, dwelt upon strongly by Newcomb in his account of the eclipse of 1878, has been re-observed. We read that this ring was seen to extend some 2,000,000 miles on either side of the sun, and to put on the appearance of two forked wings of light. Not only in 1878 was this ring-like extension well marked, but, in consequence of the extreme quietude of the sun's atmosphere at the time, the exquisite structure of the atmosphere over each pole was one of the most striking features of the eclipse. The appearance was produced by the structure of the coronas bending gracefully over from the sun's axis prolonged, that nearest the pole bending least. This or something very like it has evidently been again seen, and the photographs which have been taken by Mr. Pickering's and other parties will evidently give a good account of them.

It must be noted, too, that the American astronomers have, as might have been expected, used large telescopes. We read of 13-inch and 8 inch refractors. Nothing so large as this has ever been employed before in eclipse expeditions, but then the parties this time have not been far from their base. In one of the telegrams it is stated that Mr. Pickering's party secured twenty spectrum photographs of the corona. This, perhaps, is the best news of all; and we read, too, that the less refrangible end of the spectrum has not been neglected.

Considering the short duration of totality, the results secured reflect the highest credit upon the organizers of the parties and upon the individual observers.

RECENT WORKS ON ALGÆ.[1]

PROF. ASKENASY tells us, in a brief preface, that the Algæ collected during the voyage of the Scientific Expedition in the *Gazelle* were intrusted to him for examination, and that in the work he was assisted by Herr Moebius, by whom the greater part of the excellent figures in the plates were drawn. The remainder of the figures, with the exception of those in Plate I., were drawn by the editor, thus affording an apt illustration of the great advantage to naturalists of acquiring facility in drawing.

In the determination of the Algæ, Dr. Askenasy had the assistance of MM. Bornet and Hariot; the Characeæ and Conjugatæ were described by Dr. Otto Nordstedt, by whom the well-drawn figures in Plate I. were executed. Herr Grunow described the Cystophyllum and Carpophyllum, and the difficult genus of Sargassum.

The only new plant among the Confervaceæ is *Anadyomene reticulata*, Askenasy, from the Island of Dirk Hartog, in West Australia. The Characeæ, now included among Algæ, are rather numerous; among them are two new species of Nitella.

[1] "Forschungsreise S.M.S. *Gazelle*," iv. Theil-Botanik, Algen; mit Unterstützung der Herren E. Bornet, A. Grunow, P. Hariot, M. Moebius, O. Nordstedt. Bearbeitet von Prof. Dr. E. Askenasy. Mit 12 Tafeln. (Berlin: Ernst Siegfried Mittler und Sohn, 1888.)
"Om structuren hos Champia och Lomentaria," med anledning af nyare tydningar. Af J. G. Agardh, Öfversigt af Kongl. Vetenskaps-Akademiens. Förhandlingar, 1888, No. 2. (Stockholm.)
"Fresh-water Algæ collected by Dr. Berggren in New Zealand and Australia." By Otto Nordstedt. With 7 Plates. Communicated to the Royal Swedish Academy of Science, June 1887. (Stockholm, 1888.)

Dr. Askenasy prefaces his description of Halimeda by remarking that the structure of the genus has not been hitherto described. From this it would appear that Dr. Agardh's observations on Halimeda, contained in Part V. of his work, "Til Algernes Systematik" ("On the Classification of Algæ"), is still unknown at Berlin. It may be mentioned that, while the title is in Swedish, the work is in Latin.

The remarks of Dr. Askenasy are, however, not the less welcome, illustrated as they are by the figures in Plate IV. One new species, *H. macrophysa*, is described. It is to be regretted that so little is as yet known of the fructification of these plants.

One new species of Caulerpa, *C. delicatula*, allied to *C. Brownii*, is added to the sixty-seven species of this genus already known to science.

The Ectocarpeæ are carefully worked up, and one new species from Kerguelen's Land, *E. Constantiæ*, has been added by Dr. Hariot.

Perhaps the most interesting part of the work is the result of Dr. Grunow's study of the genus Sargassum. Every algologist is aware how difficult it is to identify the specimens, often very fragmentary, of this plant, which lie before him for examination. Fortunate is the collector who obtains a whole plant of Sargassum, comprising root and lower leaves—which often differ materially from those in the upper part of the plant—branches bearing leaves only, and other branches bearing fruit and vesicles as well as leaves. It is owing to this fragmentary state of the plants that the published descriptions are frequently defective.

Dr. Grunow has done much to elucidate the life-history of the genus Sargassum by his discovery that some species are monœcious, and others diœcious. In describing *S. Carpophyllun* (see "Voyage of the *Novara*," p. 56), Dr. Grunow mentions the occurrence on the same plant of two kinds of fruit—namely, short receptacles which correspond with those described by Dr. Agardh, and also linear receptacles three-quarters of an inch long. He, however, makes, in this work, no further observations on the subject.

In the present work he merely mentions that the plant is monœcious. It will be seen from the descriptions of the other species in the text that Dr. Grunow has been able to prosecute successfully his researches on the fruit of the Sargassa. In most cases it is indicated in the text whether the species are monœcious or diœcious. It seems to be ascertained that the smaller kind of fruit contains spores; while the antheridia are contained in receptacles nearly twice the size of the former. There also exists much diversity in the form of the receptacles belonging to the same species. The spore-bearing receptacles are sometimes forked or spiny, while those bearing antheridia are simple, smooth, and cylindrical. The list of Sargassa in the present work contains twenty-eight species and varieties. In the case of the varieties Dr. Grunow is careful to mention in what respects they differ from the original species.

As to *S. bacciferum*, it is mentioned in the text that its history is still insufficiently known. The editor refers to the pelagic specimens, called "gulf-weed," which float for a time without root or fruit, and subsequently decay; but he does not seem to be aware the *S. bacciferum* was found by Mr. Moseley,[1] during the voyage of the *Challenger*, growing plentifully and full of fruit on rocks in Harrington Sound, Bermudas. The *S. bacciferum*, var. *foliifera*, also bears fruit.

It may be remarked that while there is a general impression that no parasitic Algæ are found growing on gulf-weed, Dr. Askenasy met with a specimen among the Algæ brought home by the *Gazelle* on which were growing a *Rivularia* and a *Calothrix*, and that other epiphytic Algæ were found on the same species by Martens.

[1] See extract from Mr. Moseley's letter, dated June 27, 1873, in Dr. Dickie's paper on the marine Algæ of St. Thomas and Bermuda, Journal of the Linnean Society, vol. xiv.

Among the Rhodophyceæ of this collection, there is one new genus, *Episporium centroceratis*, Moebius. It is from West Australia, and is classed with the Cryptonemiaceæ. The new species are four in number—namely, *Hildebrandtia Lecannellieri*, Hariot; *Chaukausia Naumanni*, Askenasy; *Rhabdonia decumbens*, Grunow; and *Sarcomenia intermedia*, Grunow. Among the rarer species are *Corynospora Wüllerstorfiana*, Grunow; *Ptilota Eatoni*, Dickie; and *Marchesettia spongioides*, Hauck. A plentiful harvest was obtained of the beautiful and very rare Nitophylla and Delessericæ of the Southern Ocean.

The attention of algologists will be drawn to the minute and careful analytical descriptions of many species of the Florideæ. Great pains have been bestowed by Dr. Askenasy on the description of some species of Galaxaura: the more delicate parts of these plants, he observes, have not been described. Fruit is rare, and but imperfectly known in this genus. It may be observed that Dr. Askenasy's classification of Galaxaura differs from that of Agardh ("Til Algernes Systematik," Part vii., Florideæ). By the former it is placed among the Chætangiaceæ; the latter retains it among the Helminthocladieæ.

Dr. Askenasy gives an elaborate description of that singular production of Nature, *Marchesettia spongioides*, Hauck. He mentions it as "this plant or organism," for it seems to be between a Sponge and an Alga. It was known imperfectly to Semper and Esper. Dr. Hauck, who had found it among the Sponges in the Museum at Trieste, announced that it was an Alga, which belonged to the Florideæ, and to the group of the Areschougieæ ("Su un nuovo caso di simbiosi," *Atti del Museo Civ. di Stor. Nat. di Trieste*, 1884). In external appearance this "organism" resembles a branched Sponge; the Alga being entirely inclosed within it. Dr. Askenasy has devoted one whole plate (Plate XII.) to illustrate the Marchesettia. The fructification is at the end of the branches. Tetraspores were seen by Dr. Hauck and by Dr. Askenasy, but it is not mentioned whether they were cruciate or zonate. Dr. Agardh observed cystocarps, which he thought approximated to those of Rissoella.

On the inside of the "organism," and among the branches of the Alga, Dr. Askenasy found, in the specimens brought home by the *Gazelle* Expedition, and preserved in spirit, a slimy substance, like that which constitutes the life of a sponge, and he is decidedly of opinion that *Marchesettia spongioides* is, to use his own words, "eine symbiose zwischen einer Floridee und einer Spongie darstellt" (p. 41). Marchesettia is a native of Madagascar, Singapore, the Philippines, and New Caledonia.

The external resemblance of the Marchesettia to a species of Thamnoclonium of the section Dictyophoræ is so great that Dr. Agardh gave to the latter the name of *Th. Marchesettioides*. The plants, when in fructification, may, however, be always easily distinguished, the fruit of the Thamnoclonium being contained in leaflets, which spring from the sides of the plant.

This is a very useful work to algologists; but its utility would have been increased by the addition of an index. It may also be observed that the size of the type might have been enlarged with benefit to the eyes of students.

The subject of Dr. Agardh's essay is the structure of Champia and Lomentaria. He observes that within the space of little more than a year, four special essays—two by N. Wille, one by F. Debray, and another by R. P. Bigelow—have been published with a view to demonstrate the structure of these well-known plants, and that these publications give an entirely erroneous representation of the entire development of these Algæ. He therefore thought it expedient for him, who had published ten years ago a very different description, to state his opinion on

these new works and his own views on the subject. This he has done in the present essay.

The descriptions referred to by Dr. Agardh appeared in his work entitled, "Florideernes-Morphologi" (published in the Transactions of the Royal Swedish Academy in 1879); but as this work was written in Swedish, it has probably not met with so many readers as it deserves. With a view to make this work more accessible, Dr. Agardh issued, in 1880, a Latin translation of it.

After stating the views of the essayists, and commenting on them, he quotes the concluding words of Mr. Bigelow, the most recent of them: "We have to leave our subject for the present in an unsettled and therefore rather unsatisfactory condition."

Dr. Agardh then quotes from his Swedish work the description of the structure of Lomentaria and Champia, showing that in the young state the interior is never hollow, but is interlaced with delicate coloured filaments, which disappear in the older parts of the plants. He also mentions that some Florideæ, which are apparently hollow, such as Chrysymenia, Dumontia, &c., are in part filled with a gaseous fluid, which probably assists such plants as have thin walls in preserving an erect position.

Dr. Otto Nordstedt is already well known to British algologists by the specimens of fresh-water Algæ which he has issued in conjunction with Prof. Wittrock, of Stockholm. The work he now sends us proves that he is a good draftsman and linguist, as well as algologist. It is on the fresh-water Algæ of New Zealand, and is written in very good English, and carefully got up in every respect. The author mentions that the Desmids have received his greatest attention, and that comparatively little attention has been bestowed on the Phycochromaceæ; a few only have been taken from brackish water.

Dr. Nordstedt mentions that he has not met with any new genus of fresh-water Algæ, or with any genus not represented in Europe, with the exception of *Phymatodocis*, which, he tells us, occurs also in North and South America, and in Australia.

With regard to the localities in New Zealand where fresh-water Algæ are found, no one is better acquainted with them than Dr. Berggren, who had made an interesting collection, subsequently examined by Dr. Nordstedt, and included in the present work on these plants. Dr. Berggren's remarks, as recorded by Dr. Nordstedt, will be read with interest. He says:—

"The fresh-water Algæ in New Zealand do not, from several causes, occur so frequently as in the regions of the corresponding latitudes of the northern hemisphere. The ground, which is generally sloping, gives a rapid course to rivers and brooks, and the surface occupied by stagnant water, swamps, and bogs is not very extensive. The comparatively small number of water- and bog-plants growing sociably together (such as *Potamogeton* and others), which in the stagnant waters and marshy spots of Europe are favourable to the existence of the fresh-water Algæ, is of great consequence. The usually dry summer generally causes the draining of those lowland spots, which in the wet season (the winter) are swamps. Therefore the Algæ are more frequent in the damp and moss-grown localities of the mountainous regions in the Northern as well as in the Southern Island. In the rivulets from hot springs in the hot lake district in the Northern Island, the Algæ are especially Phycochromaceæ, but likewise Confervaceæ and Zygnemaceæ, to be found growing in great abundance."

Dr. Nordstedt mentions that from his examination of Dr. Berggren's collection, it appears that the swampy ground on the Canterbury Alps and the highlands round the Taupo Lake are the best localities, especially for Desmids.

The description of the New Zealand Algæ is supplemented by lists of a few fresh-water Algæ from Australia and the Hawaiian Islands. Then follow a list of the principal works consulted, and an index. The work is illustrated by seven plates, the figures of which are all drawn—and well drawn—by the author.

MARY P. MERRIFIELD.

THE JOURNAL OF MORPHOLOGY.[1]

THE year 1887 marked an epoch in the advance of natural science in America, as that in which the above-named journal made its appearance. The first number was not published until some months after the advertised time, but, once in circulation, it became clear to all that the delay was warranted by the eminently satisfactory result obtained. The journal was defined in the preliminary advertisement as one "devoted principally to embryological, anatomical, and histological subjects," it being stated that "only original articles, which deal thoroughly with the subject in hand, will be admitted to its pages." The three parts before us present in the aggregate 593 pages crown octavo, with thirty plates, and woodcuts interspersed with the text. Seventeen papers have in all appeared, and of these, seven or eight are devoted to embryology, with a total of 361 pages, and four or five to anatomy and histology, with that of 182 pages. One is purely experimental, and deals with the mental powers of spiders (37 pages), and another is largely palæontological (12 pages), while the three which remain (61 pages in all) are largely controversial. The illustrations are throughout most excellent, but it is surprising to what an extent the work in this department has been done in Germany, especially as it has resulted in "a great loss of time and inconvenience in supervision." We are assured, however, that "there is no remedy except in the employment of an expert lithographer, to work under our immediate direction." We sincerely hope the editors may soon see their way to the employment of such an one, for surely he is to be found in the United States.

It will be seen from the foregoing that while, in the early issues, all branches of animal biology have been represented, there is a marked preponderance of embryological literature; and, taking into account the share which the discursive papers contribute towards this subject, there would appear to be a predisposition in favour of the same. The study of embryology is one which lends itself, by virtue of its constitution, to the production of hypotheses and broad generalizations; and, in knowledge of the extent to which previous workers have often availed themselves of this, we are led to inquire how far the predisposition in question may be due to this cause. Certain of our American brethren are notorious for their power of accumulating superfluous detail. Publications could be cited in which the "padding" is inversely proportionate to the actual work done, and we would fain desire that the authors should work more and write less; indeed, the senior editor has acknowledged this. He writes: "Concentration is our need"; and further, "The inaccessibility of our literature—scattered as it is among the publications of so many societies and institutions, and mixed up with a mass of heterogeneous matter that has no value for a zoologist—is notorious." All this being so, it is not surprising that the editors have decided to issue the numbers only "as often as the requisite material is furnished."

In estimating the usefulness of a private journal such as this, especially when so largely devoted to the interests of a subject lending itself to broad generalization, we cannot refrain from deploring the tendency, elsewhere manifest, towards the introduction of a bias in favour of

[1] *The Journal of Morphology*, edited by C. O. Whitman, with the co-operation of E. P. Allis, Jun. (Boston: Ginn and Co.)

certain restricted lines of thought. We meet with indications of cliquism and faction, and it would not be difficult to show that, in respect to this and some other matters, such journals at times compare unfavourably with that of the Society, which is kept in check by freedom of discussion and by criticism at the hands of referees. Instances are not wanting to show that the elementary student, starting research, is at times turned adrift in the labyrinths of a highly-involved problem, before he knows with what he is dealing; and if, as has occasionally happened, he be working under the influence of a preconceived bias, mischievous results must accrue. Although, in the pages before us, no such instance as this is actually forthcoming, we are of opinion that, in respect to certain matters referred to below, consultation with specialists prior to publication, would have resulted in the withdrawal of heresies which constitute the only jarring element in this beautiful work.

The authors of the papers thus far published are, for the most part, men of established repute. For many of them we entertain a personal regard, and there are among their leading productions monographs that are continuations of those with which, under the old *régime*, they have honoured our national journals. Others there are with the preliminaries to which we claim a proud familiarity, and many of us look back with pleasure upon the fact that one of the original communications on the subject of the opening paper was made in our midst (cf. P.Z.S., 1886, p. 343). The journal makes its *début* under auspicious circumstances, and the above and other similar considerations show it to be the outcome of a growing want, in the unfolding of which we have ourselves had a stake; it is manifestly our duty, therefore, to support it.

The papers, when considered individually, must be declared of excellent merit, and, detailed criticism being here impossible, we pass to a brief comment upon those most conspicuous or most likely to raise discussion. Chief among all are the contributions of the senior editor. We defer mention of the more philosophic of these till the end of our notice; his "Contribution to the History of the Germ-Layers in Clepsine" (78 pages) is a marvellously-wrought piece of work; and, if his leading deductions concerning the fate of his "macromeres" be capable of support, he may well lay claim to a masterly stroke in advance. With his "teloblasts" there is initiated an entirely new line of inquiry, in itself refreshing after the ceaseless quibbles as to the fate of the "blastopore," while it gives promise of a direct and important bearing upon some of the most revolutionary of recent embryological discoveries (*e.g.* that concerning the part played by the ectoblast in the development of the excretory system). The author marshals his facts in faultless sequence: his monograph is a model of its kind, the more contemplated the more to be admired; and it fully establishes his reputation as a leader among American embryologists.

Four of the papers offered us pertain to the eye, with a total of 171 pages. The authors of these are Messrs. Patten and Kingsley, and the first of the series, by the former, is a condensation of his larger contribution to the Naples *Mittheilungen*. This paper has obtained a notoriety on account of the heated discussion which it evoked, and, setting personalities aside, we admit that the author's ill-conceived "dynamophagous organs" received, together with his more flagrant heresies, a well-deserved refutation. Many of this investigator's suggestions and aspirations are neither better nor worse than those of his critics and predecessors; he has, like many more enthusiasts, aimed at high game with a resolve to be sensational at all hazards. It must be admitted, however, on careful perusal of his work, that he erred in an over-enthusiasm, and that there underlies his remarkable production a substratum of solid fact. Excessive theorizers, like excessive controversialists, stand in a fair way of being shelved, if only by virtue of their verboseness. On examination of the later contributions of this author, we observe that he has profited by his hard-earned experience, and that he has, under the influence of his able editor, chosen the wise, though very obvious, path. The other writer on this subject produces a paper of an altogether more modest cast. In his 16 pages there are embodied a series of very useful observations and suggestions which, if ultimately accepted, will simplify our conceptions of the complex visual organ in the Arthropods. He differs from his contemporary on points of primary importance. We welcome this as a healthy sign (cf. *ante*), and the reader will find that in these papers, and others proffered in this journal, differences of opinion are asserted in inoffensive language, in a spirit as free of both animus and bias as it is becoming the dignity of the subject in hand.

Prof. Osborne contributes two most interesting papers: one, on the internal structure of the Amphibian brain, is the completion of a series of beautiful studies, largely inspired by our greatest living master (cf. *Morph. Jahrb.*, vol. xii. p. 247); the other, on the fœtal membranes of the Marsupials, is also a continuation of earlier studies, and we watch the growth of them with intense interest, in view of those so long looked for at the hands of a countryman of our own, upon the same in the Australian forms.

One of the most ambitious communications is that bearing the title, "On the Phylogenetic Arrangement of the Sauropsida." The author has elsewhere expressed many of his views on the subject; his enthusiasm and daring admitted, we cannot pass unnoticed the superficiality of his essay; in respect to this, it does not even come within the conditions imposed by the founders of the journal. More than that, however. Reference is made by the author to his order *Proganosauria;* if his primary diagnosis of the same (*Zoolog. Anzeiger*, 1886, p. 189) be compared with the original drawing (Proc. Amer. Phil. Soc., vol. xxiii. No. 121) and with the replicas in our national collection, it will be found that the existence of his leading structural peculiarity (we refer to the presence of five distinct tarsalia) is at least doubtful. Even if it did exist, the exaltation of such a character to a position of ordinal value would be unwarrantable, and, as employed by the author, meaningless, inasmuch as a fifth tarsale is present in the Chelonia. This he admits (cf. *Zoolog. Anzeiger*, 1888, p. 597), and in doing so he lands himself in a contradiction. We cannot but regret the hasty introduction of generalizations so sweeping into papers of a provisional nature, and we take this opportunity of entering a protest against this abuse of the "*vorläufige Mittheilung*": as a means of establishing a claim of priority in the discovery of a sound fact it is of the utmost utility, but as converted into a medium for contradiction it becomes intolerable. The over-cultivation of this unfortunate habit bids fair to involve its devotees in difficulties irrecoverable; the best work always has been, and always will be, done, as wrote Goethe, "*ohne Hast, ohne Rast.*" The waste which accrues from the abuse here deplored will ultimately find its own level, but its accumulation is none the less to be regretted.

In matters of *technique* this journal is not deficient. Its general "get-up" is most admirable, and full attention has been paid to minute detail: the type is excellent. The plates are faultless, and admirably arranged in relation to their accompanying explanations, and the eye is never offended by the unpardonable intrusion of a woodcut upon the margin of the page. One or two minor modifications might be suggested, but they are so trivial that we prefer not to burden this notice with them. We observe, with extreme satisfaction, that in leading papers care has been taken to discriminate between the more important representations of fact and the less important diagrams, the latter being interspersed among the text, in woodcut. The

journal will stand the test of comparison with any of its contemporaries, and the immediate promise of a series of papers on the anatomy and embryology of Amia augurs well for its future.

Prof. Cope contributes a very characteristic paper on the tritubercular molar, the leading deduction of which is most interesting and suggestive; it reads (vol. ii. p. 21): "The tritubercular molars of man constitute a reversion to the dentition of the Lemuridæ of the Eocene period of the family of Anaptomorphidæ," and "this reversion is principally seen among the Esquimaux, and the Slavic, French, and American branches of the European race." The senior editor, discussing, in the most philosophic paper of the series, "The Seat of Formative and Regenerative Energy," writes as follows: "These higher (biological) units combine both atomic and molecular structure, but they have, superadded to and including this, a structure as a whole, which is entirely ignored in the expression, 'molecular aggregates.' As they result from the union, not of simple or complex molecules, but of complex molecular groups, their structure may be said to be at least as widely separated from the molecule as this is from the atom"; and, further, "in claiming that 'physiological units' have something higher than molecular structure and power, I am not treading on ultra-scientific ground, but following the course already sanctioned by chemistry and physics, and the only one which can ever reconcile physico-chemical and biological conceptions." We heartily recommend this valuable essay to our readers, for the author's contentions in defence of his belief that "the organism as a whole controls the formative processes going on in each part," are worthy of all the consideration that can be given them. He appears to us to underestimate the importance of recent advance in organic chemistry. The work of unravelling the constitution of the more complex organic bodies—a work in which certain of our own countrymen are playing a leading part—gives us hope beyond that which he entertains. The presence of the above-cited remarkable passages is, in itself, sufficient to invest the early numbers of this journal with a lasting interest.

We congratulate the editors upon their enterprise; they are supported by influential friends and surrounded by enthusiastic investigators; they have, in turn, fulfilled, thus far, the highest expectations of their most sincere well-wishers, and merited the confidence and support of the biological brotherhood throughout the world.

G. B. H.

THE BALD-HEADED CHIMPANZEE.

THERE is no longer any room for doubt amongst naturalists as to the complete distinctness of the larger anthropoid ape of tropical Africa, the gorilla, from its smaller brother, the chimpanzee. The differences are amply sufficient for specific, if not for generic, distinction. But, on the question whether there is only one chimpanzee, spread over a great extent of the African continent, or several species confounded under the same name, there is still much difference of opinion. As long ago as 1853, M. Duvernoy communicated to the Academy of Sciences of Paris a short description of a second species of chimpanzee (see *Comptes rendus*, vol. xxxvi. p. 927), based on specimens obtained by Dr. Franquet in Gaboon in 1851. M. Duvernoy subsequently published an elaborate memoir on the same subject in the *Archives du Muséum* (vol. viii. p 1). The distinctions insisted upon by Duvernoy between his *Troglodytes tschego* and the ordinary *T. niger* were chiefly osteological; at the same time he characterized the *tschego* (from M. Franquet's description) as having the "face black, and the ears small," while, according to the same authority, the ordinary chimpanzee has "very large ears, and its face flesh-coloured."

In 1858, in a memoir also published in the *Archives du Muséum* (vol. x. p. 94), on the specimens of anthropoid apes in the Paris collection, M. Isidore Geoffroy St. Hilaire published a letter from Dr. Franquet in which the latter again insisted on the differences of the three species of anthropoid apes observed by him in the district of Gaboon. These were characterized as follows:—

(1) The *Chimpanzee*, with the face flesh-coloured, the ears red and large, and the fur black.

(2) The *Gorilla*, with the face black, the ears small and black, and the fur of a brownish chestnut, but varying in tint in different parts of the body, and with always a row of reddish hair starting from the middle of the forehead and following the line of the sagittal suture.

(3) The *N'tchego*, with the face black and the ears small, as in the gorilla. The hairs of this ape, he says, are shorter and darker in colour, and it never attains the size of the gorilla, or carries the red crest across the forehead.

In 1860, the well-known traveller Mr. P. B. Du Chaillu gave his account of the anthropoid apes of the Gaboon to the Boston Society of Natural History (see Proceedings of that Society, vol. vii. p. 296). Mr. Du Chaillu described, as a new species of chimpanzee, *Troglodytes calvus*, "with the head entirely bald to the level of the middle of the ears behind," and "having large ears," while he identified the *N'tchego* of Dr. Franquet as being nothing but the adult chimpanzee (*T. niger*). In a second communication to the same Society (*op. cit.* p. 358), he described another new species of chimpanzee, with a black face, but the forehead not bald, which he called *Troglodytes kooloo-kamba*, from its peculiar cry.

In 1861, the late Dr. J. E. Gray examined Mr. Du Chaillu's specimens of apes, and came to the conclusion that both his supposed new species were only varieties of the common chimpanzee (see P.Z.S., 1861, p. 273). Such also, as was stated by Dr. Gray, was my own opinion at that time, and I have remained in a doubtful state of mind on the subject until a recent period. But the acquisition of the fine female specimen of chimpanzee, generally known by the name of "Sally," by the Zoological Society in 1883, caused me to change my views very materially. There can be no doubt that this animal, when compared with specimens of the ordinary chimpanzee, presents very essential points of distinction. The uniform black face and nearly naked forehead, which is only covered with very short black hairs, together with the large size of the ears, render "Sally" conspicuously different from the many specimens of the common chimpanzee (at least thirty in number) that the Society has previously received. I was at first inclined to believe that "Sally" might be referable to the *Troglodytes tschego* of Duvernoy. But nothing is said, in M. Duvernoy's description, of the bald forehead; and the small ears attributed to the *N'tchego*, are directly contrary to this hypothesis, as in "Sally" these organs are exceedingly large and prominent. On the whole, I was inclined to believe that "Sally" might belong to the *Troglodytes calvus* of Du Chaillu, and she was accordingly entered in the Register of the Society's Menagerie as the Bald-headed Chimpanzee (*Anthropopithecus calvus*[1]), which is certainly a very appropriate name, even if it be not technically correct.

In the beginning of the present month we purchased of Mr. Cross, of Liverpool (from whom we had also obtained "Sally"), a second specimen of the Bald-headed Chimpanzee, likewise a female, which, although much smaller in size, closely resembles "Sally" in every other respect.

Fortunately, there is now in the Gardens a young specimen of the Common Chimpanzee (*Anthropopithecus troglodytes*), presented to the Society in May last by

[1] The term *Troglodytes* being more properly used for a genus of birds, it becomes necessary to employ for the chimpanzees the generic term "*Anthropopithecus*," of Blainville, as suggested by Peters in 1876.

Mr. F. J. Aldridge, F.Z.S., by whom it was brought from Sierra Leone. This specimen is of about the same size and age as the young Bald-headed Chimpanzee, and enables an easy comparison to be made between the two species. Looking first at *A. calvus*, we find the skin of the head, face, ears, and limbs of a dark brownish clay colour, which will, no doubt, get blacker as the animal becomes adult. The ears are perfectly naked, and of large size, and stand out at nearly right angles from the head. The top of the head is very scantily covered with short blackish hair. The whole of the body and limbs are also very thinly covered with hair, especially the abdomen.

When we turn to the young specimen of *A. troglodytes*, we find the upper part of the face and the brows of a dirty flesh colour. Between the eyes, above the nostrils, and passing down the cheeks, it is black. The nose and muzzle are of a dirty flesh colour. The chin and upper lip are covered with longish white hair. The inside of the ears is nearly black. The forehead, cheeks, and the whole of the body are covered with long, harsh, black hair. The colour of the hands and feet are of a brownish clay colour, much the same as those of *A. calvus.*

The rump above and below the anus is covered with longish white hair.

With regard to the size of these two animals, the length of limbs, and other measurements, they are nearly equal. It is probable that *A. troglodytes* is a trifle older than the new specimen of *A. calvus.*

It may be of interest to mention that, as Mr. Bartlett informs me, the young *A. calvus* will kill and eat sparrows in the same manner as "Sally" kills and eats pigeons, whereas the common chimpanzee will not touch any food of this kind.

It must be admitted, however, that the specific term *calvus*, applied to "Sally" and her "younger sister," can only be considered as provisional. When these specimens die, which, we trust, will not be till some distant period, they must be compared with the example of the *Troglodytes calvus* of Du Chaillu, which is now in the British Museum. On the same occasion the skulls of these specimens can be compared with the descriptions and figures given by Duvernoy of his *Troglodytes tschego.* Until this can be done, it is impossible to say decisively whether these two specimens belong to one of the supposed species already described, or should receive a new name.

Finally, I may add that the Ape House in the Society's Gardens, besides these two chimpanzees, contains at the present time a young female Orang (*Simia satyrus*), received on deposit, and a specimen of the Silvery Gibbon (*Hylobates leuciscus*), lately presented by Captain D. L. Delacherois; so that all the three known genera of anthropoid apes may be now seen represented by living specimens. P. L. S.

NOTES.

A MOVEMENT has been started in Norway for the despatch in the summer of 1890 of an Expedition which would try to reach the North Pole, and it is proposed that the leadership shall be offered to Dr. Nansen. Those who are arranging the plans maintain that no other country could furnish such a crew of experienced and hardy ice-men and Arctic travellers as Norway, and that a winter or two in the Arctic regions would affect these men very little. The intention is that an attempt shall be made to reach the Pole by way of Franz Josef's Land, a route advocated by the most experienced Norwegian Arctic travellers as well as by several well-known men of science who have studied the problem. *Ski*, which have played such a prominent part in the Nordenskiöld and Nansen Greenland expeditions, would no doubt again be of great service.

THE Royal Academy of Sciences of Turin, in accordance with the last will and testament of Dr. Cesare Alessandro Bressa, and in conformity with the programme published on December 7, 1876, announces that the term for competition for scientific works and discoveries made in the years 1885–88, to which only Italian authors and inventors were entitled, was closed on December 31, 1888. The Academy now gives notice that from January 1, 1887, the new term for competition for the seventh Bressa Prize has begun, to which, according to the testator's will, scientific men and inventors of all nations will be admitted. A prize will therefore be given to the scientific author or inventor, whatever be his nationality, who during the years 1887–90, according to the judgment of the Royal Academy of Sciences of Turin, shall have made the most important and useful discovery, or published the most valuable work on any of the following subjects—physical and experimental science, natural history, mathematics, chemistry, physiology, pathology, geology, history, geography, and statistics. The term will be closed at the end of December 1890. The value of the prize amounts to 12,000 Italian lire. The prize will in no case be given to any of the national members of the Academy of Turin, resident or non-resident.

THE Board of Electors to the Linacre Professorship of Human and Comparative Anatomy at Oxford have, on account of Prof. Moseley's continued illness, nominated Mr. W. Hatchett Jackson, M.A., F.L.S., to serve as Deputy Professor.

SIR HENRY ROSCOE has been elected to represent the Royal Society on the governing body of Eton College.

WE regret to announce the death of Mrs. Merrifield, whose name as a writer on Algæ and kindred subjects is well known to our readers. She died on January 4, in her eighty-fifth year. To-day we print an article by Mrs. Merrifield on some recent works on Algæ. We learn that she was very ill when this article was written, but it was not thought that the end was so near.

THE annual general meeting of the Royal Meteorological Society will be held at 25 Great George Street, Westminster, on Wednesday, the 16th instant, at 7.15 p.m., when the report of the Council will be read, the election of officers and Council for the ensuing year will take place, and the President (Dr. W. Marcet, F.R.S., will deliver an address on "Fogs," which will be illustrated by a number of lantern slides.

In the January number of the *Kew Bulletin* there is a most interesting paper on the coca-plant, to which considerable attention has lately been devoted, mainly because of the valuable properties ascribed to one of its alkaloids, called cocaine, as a local anæsthetic. It appears that since the discovery of the anæsthetic properties of cocaine the demand for coca-leaves in South America has considerably increased for export purposes. A distinct loss in the alkaloids generally, as well as in cocaine, has been noticed during the transit of leaves to this country; and latterly, in consequence, it has become the practice to extract the alkaloids from the leaves in South America, and export to the United States and Europe a crude preparation, which is largely taken up by manufacturers of cocaine. The demand for coca-leaves has, therefore, fallen off, and the writer of the paper thinks that the cultivation of the coca-plant in our tropical colonies will probably never assume large proportions. South America, he says, is able without further extension of cultivation to produce such enormous quantities of coca-leaves that the one-eightieth part would be sufficient to swamp the cocaine markets of the whole world. The other subjects dealt with in this number are beetles destructive to rice-crops in Burmah, fibre from Lagos, yam bean, Schweinfurth's method for preserving plants, a starch-yielding bromeliad, and the fruits of Mysore.

The Swedish Superintendent of Fisheries, Dr. F. Trybom, has, at the instance of the Swedish Government, been engaged during the past autumn in making a series of scientific experiments on the coast of Sweden for the purpose of studying the condition of the herring when undisturbed. He brought back with him newly-hatched herring-fry and herring-spawn ready to be hatched. The bottom on which these were found consisted of stones, gravel, and shells; the depth of water was about 20 metres, and the temperature of water at the bottom about 11° C. The results of these experiments are not yet known, but a Swedish paper says that they are such as to encourage the Government to permit Dr. Trybom to continue next autumn his inquiries into the development, habits, and habitats of the most important fish on the Swedish coasts.

Dr. Kolthoff, the well-known Swedish naturalist, is arranging an interesting zoological museum at the Upsala University, being a complete representation of the fauna of Scandinavia, with nests, representations of lairs, &c. This is the only museum of the kind in Sweden.

Gaseous fluoride of methyl has been obtained in the pure state, and its density determined, by MM. Moissan and Meslans. The existence of this gas was announced some years ago by MM. Dumas and Peligot, who describe a mode of preparation by the action of methyl sulphuric acid upon fluoride of potassium. The gas obtained, however, by this method is now shown to be a mixture of oxide and fluoride of methyl, and a new method has been developed by means of which it is obtained sufficiently pure for accurate analysis. The reaction is analogous to the one recently described for the preparation of ethyl fluoride, methyl iodide being allowed to act upon fluoride of silver. A regular evolution of gas commences at once in the cold, and the gaseous mixture, consisting of methyl fluoride and vapour of methyl iodide, is led first through a spiral leaden condenser cooled to − 50° C., where most of the latter substance is condensed, and afterwards through a couple of glass tubes heated to 90° and filled with fresh fluoride of silver, which removes the last traces of methyl iodide. This reaction is found to be the only one yet known which gives the gas in anything like a state of purity. MM. Moissan and Meslans have, however, also obtained it in a lesser degree of purity by the action of pentafluoride of phosphorus upon methyl alcohol. The fluoride of methyl obtained as above possesses a normal density corresponding to the formula CH_3F. It liquefies at ordinary temperatures when submitted to a pressure of thirty-two atmospheres in Cailletet's apparatus. It is slightly soluble in water, 100 c.c. at 18° dissolving about 193 c.c. of the gas; it dissolves very much more readily in methyl iodide or methyl alcohol. Perhaps the most interesting fact about it is its great stability, for, even on heating in sealed tubes at 120° in presence of water or a dilute solution of potash, it saponifies only with great difficulty.

Besides the above-described fluoride of methyl, another entirely new one, isobutyl fluoride, C_4H_9F, has been prepared by acting in a similar manner upon silver fluoride with isobutyl iodide. One scarcely knows whether to describe this new fluoride as a gas or a liquid. As a matter of fact, at this time of the year it is a colourless and very mobile liquid, but in summer weather would be a gas, inasmuch as its boiling-point is just about the temperature of an ordinary room, 16° C. The reaction between isobutyl iodide and silver fluoride commences vigorously in the cold, but the mixture requires warming to 50° in order to obtain a theoretical yield. In the form of a gas it burns on ignition, with deposition of carbon and formation of clouds of hydrofluoric acid. The liquid, when pure, is singularly incapable of attacking glass. It is interesting that M. Moissan has now succeeded in preparing, by means of the silver fluoride reaction with the iodides of the corresponding organic radicals, the fluorides of methyl, ethyl, propyl, and butyl, finding them in each case remarkably more stable than the analogous chlorine compounds.

In the latest volume of the American Consular Reports it is stated that Switzerland has followed other civilized countries in adopting a law for the protection of inventions. This law cannot have effect until it has been decided whether 30,000 voters will petition against it, in which case it must be submitted to the people. The American Consul states that it contains several new and interesting provisions, and he gives, in his Report, the text of the law. It is remarkable that only material objects, and not processes, are protected. This peculiarity is said to be due to the efforts of manufacturers of aniline colours and chemicals, who would be injuriously affected by a law which would protect arts as well as tools and machines. The duration of a patent is to be fifteen years; a fixed fee of 20 francs must be paid for the first year, and a progressive annual fee, which amounts in the fifteenth year to 160 francs.

A severe shock of earthquake, accompanied by loud subterranean noises, occurred on December 26 at a part of the Vogtland; it was also felt at Röttis, Lengenfeld, Plauen, and Auerbach. Shocks also occurred at Messina, Jagonegro, and Castroreale on the same day, but no serious damage was done.

The anomalies of weather felt in October and November last in Western Europe were also felt in Russia and Central Asia. From October 27 to November 13, at several places in Northernt, Eastern, and Southern Russia, the daily averages were below the normal temperatures of the same days by no less than from 16° to 19° C. On October 28, it was freezing at Tashkent early in the morning. Most Russian rivers were covered with ice from seven to twenty-five days earlier than they have been frozen on the average for a long series of years. Two great waves of cold could be distinguished, both spreading from the north-west to the south-east. In the second part of November there was a sudden return of warm weather, and the Russian rivers were opened again. Throughout this disturbed period the barometer gave valuable indications as to the movements of the cyclones and anticyclones. The centre of the latter moved as follows: on November 5, it was at Pinsk (782 mm. of barometric pressure, reduced to the sea-level); next day it was at Kherson (782 mm.); on November 5, at Pyatigorsk (781 mm.); and next day, at Erivan in Armenia (779 mm.) The height

reached by the barometer at Pyatigorsk was greater than it had ever before been known to be. As to the low pressures of the air, which soon followed the high pressures, they were not less remarkable. Thus, a pressure as low as 723 mm. was measured at Christiansund on November 19; 716 mm. at Nikolaistad (Wasa), and 720 mm. at Kuopio, on November 20; and 721 mm. at Povyenets, in Olonets, on November 21. So low a pressure as 716 mm. (reduced to the sea-level) is of exceedingly rare occurrence. The next minimum of pressure came on November 25, and it was accompanied by frightful storms which blew over Central Russia. The barometer did not fall so low as during the preceding days, but the displacement of the minimum was characterized by a further decrease of pressure in proportion as the centre of the depression advanced towards Central Russia. Like cases were observed also in 1881 and 1886, but they are rare on the whole. On November 25, the barometer at Moscow was as low as 723·8 mm.

At the meeting of the French Meteorological Society, on December 4 last, the President stated that the Minister of Commerce and Industry had appointed a Committee of Organization for the proposed Meteorological Congress to be held in 1889. The Committee met on November 24, and elected M. Renou as President, and M. L. Teisserenc de Bort as General Secretary. M. Moureau, Secretary of the Society, presented the results of magnetic observations made by him in the western basin of the Mediterranean by direction of the Minister of Public Instruction. M. Renou presented a Report by M. Cœurdevache on the relations of temperature and wind direction at Clermont and the summit of the Puys-de-Dôme during winter. He pointed out that the isotherms at the summit of the mountain are not parallel to those in the plain, the latter being influenced by various agencies, such as sea or mountain. M. L. de Bort stated that it was proposed to hold a meeting of meteorologists at Hamburg, with the view of preparing the basis of an understanding as to the classification of clouds. He thought that "nimbus" and "cumulus," especially, were a source of confusion in cloud observations, and that the height of clouds was much exaggerated in rainy weather. It had been observed that the Eiffel Tower, which now reaches over 670 feet, was frequently enveloped in cloud at a height of about 520 feet. M. Lemoine made some remarks upon the bad effect of the low summer temperatures upon the grape harvest, the first frosts occurring in many cases before the grapes had reached maturity.

The volume of *Abhandlungen und Berichte des K. Zoologischen und Anthropologisch-Ethnographischen Museums zu Dresden* (Friedländer and Son, Berlin)—in which there is a German translation of Mrs. Nuttall's article on a relic of ancient Mexico (referred to in another column)—contains, in addition to this translation, some interesting and valuable papers. It opens with a full account, by Dr. A. B. Meyer, the editor, of certain new arrangements for the better protection and display of objects in the Zoological and Anthropological Museum of Dresden. The editor also gives a list of the Reptilia and Batrachia collected by him in the East Indian Archipelago in the years 1870–73. There are papers on mammals from the East Indian Archipelago, by Dr. B. Hoffmann; on the Indian-Australian Myriopoda, by Dr. Erich Haase; and on other subjects. The volume is carefully illustrated.

Prof. R. Meldola, F.R.S., has in the press a work on "The Chemistry of Photography," which will shortly be issued by Messrs. Macmillan and Co., as one of the volumes of "Nature Series." The work consists of a course of lectures delivered last year at the Finsbury Technical College. The chief object kept in view by the author is the necessity for the full recognition of photographic chemistry as a branch of applied science in technical Colleges. Each lecture is followed by an appendix containing hints for the experimental illustration of the subject by means of lecture demonstrations, many of which are new, and all of which have been revised with a view of enabling lecturers to demonstrate the chemical principles of photography before an audience in a simple manner. The mode of treatment adopted will, it is anticipated, be found of use also to practical photographers, by enabling them to obtain a concise and comprehensive view of the scientific principles of their art.

Messrs. Crosby Lockwood and Son have issued a waistcoat-pocket book abounding in tables and concise information on a variety of topics connected with rural affairs, revised by Prof. Fream, of Downton Agricultural College. The title is "Tables, Memoranda, and Calculated Results for Farmers, Graziers, Agricultural Students, Surveyors, Land Agents, Auctioneers, &c.," by Sidney Francis. The contents are trustworthy and useful, and are readily found by means of a detailed index. It would be difficult to enumerate even the principal subjects dealt with in this cubic inch of printed matter; but we may say that, whether the inquirer opens it in order to find the composition of foods, fertilizers, or crops; the rules of measurement for animals, hay-stacks, timber, or water-courses; the strengths of materials; the advantages of water, steam, or horse power; the value of tillages, of tithes, or of woodlands; particulars as to piece-work, or costs of embanking, excavating, &c.,—he will find statistics on all these, and countless other subjects.

Messrs. Crosby Lockwood and Son have published a second edition of "The Blowpipe in Chemistry, Mineralogy, and Geology," by Lieut.-Colonel W. A. Ross, R.A. In this edition the work has been revised and enlarged. It contains 120 illustrations by the author.

We have received "The Mining Manual for 1888," compiled by Mr. Walter R. Skinner. The object of this work is to give the fullest possible information with regard to mining companies. The compiler mentions that, without reckoning South African mines, he has referred to 900 companies. Owing to the growing importance of mining at the Cape, Natal, and the Transvaal, a separate section on South African mines has been added.

In "The Floral King; a Life of Linnæus" (W. H. Allen and Co.), Mr. Albert Albery has presented a very good sketch of the career of the great Swedish botanist. It includes a number of interesting extracts from the late Dr. Ährling's selection from the correspondence of Linnæus.

Mr. John Murray has issued an interesting little book on "The Invisible Powers of Nature," by E. M. Caillard. Its object is to create in its readers a sufficient interest in physical science to lead them to the study of more advanced works on the subject.

A second edition of "Nature's Fairy-Land," by H. W. S. Worsley-Benison (Elliot Stock), has just been published.

Messrs. E. A. Petherick and Co. have published "A Classified List" of Mr. S. W. Silver's collection of New Zealand birds at the Manor House, Letcomb Regis. Sir Walter Buller has added short descriptive notes for the information of visitors. The value of the "List" is greatly increased by a number of woodcuts, most of which are borrowed from Sir Walter Buller's "Birds of New Zealand." Mr. Silver's collection consists of birds contained in twelve cases. Of these cases eight were on view in the New Zealand Court at the Colonial and Indian Exhibition in 1886. The four cases since added contain many of the rarer species of New Zealand birds.

In the current number of the *Mineralogical Magazine and Journal of the Mineralogical Society* there is a valuable article,

by Mr. H. A. Miers, entitled "Contributions to the Study of Pyrargyrite and Proustite." The paper, as the author explains, is the result of a study of the rich collection of red silvers in the British Museum (Natural History). The analyses have been made by Mr. G. T. Prior, and the specific gravity determinations in most instances by both Mr. Prior and Mr. Miers himself. The number also includes a paper on a peculiar variety of hornblende from Mynydd Mawr, Carnarvonshire, and a note on picrite from the Liskeard district, both by Prof. Bonney; a paper on dufrenite from Cornwall, by Prof. Kinch; and notes on some minerals from the Lizard, by Mr. J. J. H. Teall.

THE following figures show the devastations caused in the Hungarian vineyards by the Phylloxera. In 1881, 50 vineyards were infected; this number rose in 1882 to 79, in 1883 to 107, in 1884 to 237, in 1885 to 388, in 1886 to 582, and in 1887 to 811. In 1887, 132,352 acres of land were infected, the area of all the Hungarian vineyards together being 740,000 acres.

A LIST of the minerals of New York County, by B. B. Chamberlain, appears in the Transactions of the New York Academy of Sciences, vol. vii. No. 7. This list has now been reprinted. The lists of Robinson and Cozzens numbered some thirty-five minerals. That of Mr. Bailey, in 1865, embraced about forty-five titles. Mr. Chamberlain, omitting some of the less important varieties, has placed on record about a hundred names. The majority of the specimens described are from his own collection.

IN an interesting paper on the decay of the building-stones of New York City, recently read before the New York Academy of Sciences, Mr. Alexis A. Julien says it is "pitiable" to see new buildings erected in soft and often untried varieties of stone covered with delicate carvings of foliage and flower garlands, which are almost certain to be nipped off by the frost before the second generation of the owner shall enter the house. Mr. Julien points out that many of the best building-stones of America have never been brought into New York. Among the examples he mentions are siliceous limestones of the highest promise of durability, allied to that employed in Salisbury Cathedral; refractory sandstones, like some of those of Ohio and other Western States, particularly fitted for introduction into business buildings in the "dry-goods district," storage houses, &c., where a fire-proof stone is needed; and highly siliceous varieties of Lower Silurian sandstones, such as occur near Lake Champlain, quartzitic and hard to work, like the Craigleith stone of Edinburgh, and possessing the valuable qualities of that fine stone, in resisting discoloration, notwithstanding its light colour, and in remarkable resistance to disintegration.

THE French *Revue des Colonies* reports that from a plant called *Kanaff*, which grows in the summer on the shores of the Caspian, M. O. Blakenbourg, a chemist, has obtained an admirable textile matter, which is soft, elastic, tough, and silky, and which can be bleached chemically without losing these properties. The resistance of this new material is said to be far greater than that of hemp, while its specific weight is much less.

PROF. HEYDECK, of Königsberg, has been lecturing on a pile dwelling, in the Szontag Lake, in East Prussia. Ten years ago, the lake was lowered a little more than a metre. The land thus gained was cultivated, and a pile dwelling was discovered. Many flint implements were found. There was only one bronze ornament, but articles of bone were numerous. There were also vessels of clay, of which nineteen were quite uninjured.

IN our review of "The Orchids of the Cape Peninsula," by Harry Bolus, F.L.S., last week, it was noted that the omission of the publisher's name might cause inconvenience to persons wishing to purchase copies. Messrs. Wesley and Son write to us that some copies of the work have been sent to them for sale.

THE additions to the Zoological Society's Gardens during the past week include an African Zebu (*Bos indicus* ♀) from East Africa, presented by Mr. W. Mackinnon, F.Z.S.; a Coot (*Fulica atra*), British, presented by Mr. J. Cutting; a Greek Partridge (*Caccabis saxatilis*) from Bussorah, presented by Mr. Harold Hanaeur, F.Z.S.; two Red and Yellow Macaws (*Ara chloroptera*) from South America, a Greater Sulphur-crested Cockatoo (*Cacatua galerita*), a Roseate Cockatoo (*Cacatua roseicapilla*) from Australia, presented by Lady Meux; a —— Guinea Fowl (*Numida* ——) from East Africa, presented by Mr. Percy C. Reid; three Ruffs (*Machetes pugnax*), two Snow Buntings (*Plectrophanes nivalis*), British, purchased; a Great Wailaroo (*Macropus robustus*), born in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1889 *JANUARY* 13-19.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on January 13

Sun rises, 8h. 3m.; souths, 12h. 9m. 6·8s.; sets, 16h. 15m.: right asc. on meridian, 19h. 41·8m.; decl. 21° 24′ S. Sidereal Time at Sunset, 23h. 48m.

Moon (Full on January 17, 6h.) rises, 13h. 35m.; souths, 21h. 31m.; sets, 5h. 36m.*: right asc. on meridian, 5h. 5·2m.; decl. 19° 52′ N.

Planet.	Rises. h. m.	Souths. h. m.	Sets. h. m.	Right asc. and declination on meridian. h. m.	° ′
Mercury..	8 45 ...	12 52 ...	16 59 ...	20 25·2 ...	21 22 S.

GEOGRAPHICAL NOTES.

AT the Royal Geographical Society on Monday night, a paper was read by Mr. F. S. Arnot on his journey from Natal to Bihé and Benguella, and thence across the central plateau of Africa to the sources of the Zambesi and the Congo. Mr. Arnot reached Natal in September 1881, and has only just returned from his seven years' wanderings, during which he crossed the continent to some extent in the route of Livingstone. His paper forms an important supplement to the work of Livingstone, Cameron, Ivens and Capello, and the German traveller Reichart. Crossing from Natal obliquely, he struck the Zambesi near Sesheke, and ascended the river to Lealui, the town of Liwanika, to endeavour to persuade the chief to let him proceed northwards among the Batonge and Mashashe. Unsuccessful in this, Mr. Arnot left Lealui in May 1884, and proceeded to Bihé and the coast. Returning to Bihé, Mr. Arnot proceeded eastwards, crossing the interesting country from which so many rivers take their rise, flowing north, south, and west, to the Congo, the Zambesi, and the Atlantic. He touched Lake Dilolo, which he has reduced to very small dimensions, and has done something to rectify our knowledge of the sources of the Zambesi. The main stream, according to Mr. Arnot, comes from the east, and of this the Leeba is only a tributary. He stayed for two years at the capital of the kingdom of the chief Msidi, of whom and his government he gives an interesting account. Here he was in the region of the sources of the Lualaba. Msidi, who is really a native of Unyanyembe, seems a man of some ability, and is rapidly extending his power. He and Kangombe between them have almost swallowed up the once powerful kingdom of Muata Yanvo. Mr. Arnot returns to the Bangweolo region in March next.

DR. MEYER, and his companion Dr. O. Baumann, who were recently compelled by the hostility of the natives in East Africa to take flight to the coast, actually succeeded in crossing the country of Usambara by a new route. After marching through Bondei to the mission station of Magila, they travelled for several days through a fertile, and in places thickly-wooded depression, which forms part of the Sigi basin, reaching Hanon on September 8. Crossing the Mielo Ridge they descended into the valley of the Kumba River, and on September 18 reached the valley of Mlalo, where the Umba River runs. This region is well cultivated, and covered with numerous and large villages. Proceeding to Masende, Dr. Baumann with some natives explored the mountains, arriving eventually at a fertile region inhabited by the Wambunga. These people differ completely from the Washamba of Usambara, and are a remnant of the aborigines of the mountains, speaking a dialect similar to the Kiparé.

FROM the new volume of the *Geographische Jahrbuch* we learn that there are now 101 Geographical Societies in the world. Of these, France and her colonies have more than any other country,—29, with 19,800 members; next comes Germany, with 22 Societies, and 9200 members; followed by Great Britain and her colonies with 9 Societies, and 5600 members. There are altogether 130 geographical serials published in the various countries of the world.

M. JEAN CHAFFANJON, the explorer of the Orinoco, we learn from the *Scottish Geographical Magazine*, is about to undertake a new task. He is going to explore the peninsula and lake of Maracaibo. A tribe of Indians live in the peninsula, concerning whom no scientific data have been obtained, for they allow no one to go among them. M. Chaffanjon will try to penetrate this mystery. He will also examine the lacustrine dwellings of an extinct race in the Maracaibo Lake, and then, following the chain of the Andes, will ascend to the source of the Magdalena, cross the group of mountains which separates this river from the Rio Canca, and explore the latter down to Antioquia.

SOME ANNELIDAN AFFINITIES IN THE ONTOGENY OF THE VERTEBRATE NERVOUS SYSTEM.

IN the controversy respecting the ancestry of the Vertebrata the nervous system has always played an important part: that system is—I think Prof. Wiedersheim was the first to say it—the most aristocratic and conservative of all the organ systems of the animal body, and it clings to ancestral traditions more than any other. Anyone who has read Kleinenberg's marvellous account of the complicated manner in which the permanent nervous apparatus of the Annelid worm is built up from that of the larva (in which process of building up it passes through stages which can only be looked upon as ancestral), will readily agree that if we are ever to trace the ancestry of Vertebrates at all, the nervous system will probably form a significant factor in the solution.

The attempts made hitherto to homologize the nervous system of Vertebrates, either in the embryo or in the adult, with that of some Invertebrate or other, do not appear to have met with much success. To take one of the most recent of these. Prof. Hubrecht has, at the close of his *Challenger* Report on the Nemertines, indicated what he would regard as points of homology between the nervous system of this group and that of Vertebrates. The comparison is, in my opinion, exceedingly strained, and indeed it would not be difficult to show that it is absolutely erroneous.

The theory of the descent of Vertebrates from animals allied to the Tunicata was, as is well known, partially based on certain characters of the nervous system in the Tunicate larva; but that theory can now hardly be defended, since Dohrn has adduced powerful arguments for putting the descent the other way about—*i.e.* from Vertebrates to Tunicata—by insisting that the structure and development of Tunicata prove them to be degenerate Vertebrates.

As a third alternative we have a descent offered us by Bateson from Balanoglossus-like animals, with gill-clefts and a nervous system and notochord resembling that of Vertebrates. Many zoologists see the main and only resemblance between Balanoglossus and Vertebrates in the possession of gill-clefts. It is many years now since these structures in the two groups were first compared, and the supposed relationships between them more recently insisted upon do not seem to me to be of a very stable order. The nervous system and notochord of Balanoglossus are to be excluded from the comparison simply because they are on the hæmal side of the body, and therefore cannot be compared to structures which, like the nervous system and notochord of Vertebrates, are *not* on the hæmal side. As I am here only considering the claims of the nervous system to an homology, I cannot fully discuss the gill-clefts of Balanoglossus, and need only remark that a respiratory function of some part of the alimentary canal—generally the anterior part—is very commonly met with in many classes of the animal kingdom. Now, gill-clefts alone, without sense-organs, skeleton, nerves, or muscles (and these have not been described yet for Balanoglossus), are merely the results of a gut respiration, the alimentary tract having acquired openings on the lateral surface of the body, and it is by no means improbable that such openings could be acquired independently in two groups of animals otherwise widely separated. Two such groups are Balanoglossus and the Vertebrata.

The only remaining theory[1] of Vertebrate ancestry demanding consideration is that of Semper and Dohrn, which would derive those animals from Annelid worms. The first comparison concerned the nephridia; and it is to be remarked that the nervous system, the question of the homology of which has not been left in the background, has always been the great obstacle in the way of its acceptation, for no one has, as yet, succeeded in finding, in the Vertebrate, any homologue of the Annelidan supra-œsophageal ganglion. There have been plenty of wild and improbable speculations as to its whereabouts. A new era, however, opens with Kleinenberg's hint that possibly the supra-œsophageal ganglion of Annelids is suppressed even in the ontogeny of Vertebrates; and, if we concede this, we must look to the ventral chain of the Annelids as typifying the initial structure from which the central nervous system of Vertebrates arose. And now what points of agreement have been discovered between these two structures and their related nerves and sense-organs?

Eisig has compared the lateral sense-organs of Capitellidæ, which are segmentally arranged along the whole body of the animal, with the lateral sense-organs of Vertebrates. The latter arise in the head, and are at first confined to the head metameres: later they grow on to the trunk; they there become also segmental, but they are innervated by a true cranial nerve. Now, although Dr. Eisig's comparison is a very enticing one, it can be neither accepted nor rejected without further inquiry. There are many facts for it and some very important ones which, though not directly opposed to it, are not in its favour. We must attach a good deal of importance to it, for the

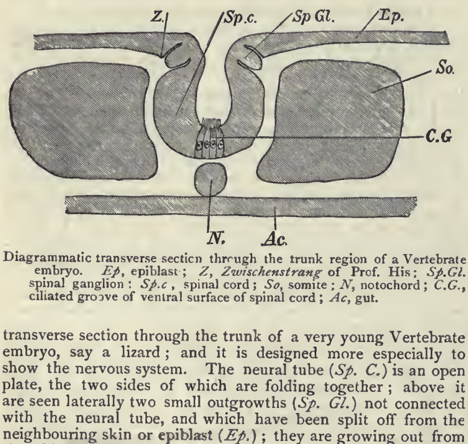
[1] Balfour ("Elasmobranch Fishes," p. 171) enunciated a different theory which can hardly now be maintained.

sense-organs of these Annelids are the only ones of which we know they in any way fulfil the conditions required of the ancestry of the lateral sense-organs of Vertebrates. It appears also that, if we admit the proposed homology as based upon the Capitellidæ, we can carry the origin of the lateral sense-organs of both groups back to still simpler structures, for it seems clear that the lateral sense-organs of Annelids have been derived from cirri and portions of the parapodial ganglia (Kleinenberg, Eisig). The rest of the Vertebrate sense-organs are easily accounted for. It is becoming more and more probable that the nose and ear are modified portions of the system of lateral sense-organs, and I am not without hopes of showing that the taste-buds of the higher Vertebrates may be derived from lateral sense-organs which wandered through certain of the gill-clefts during the development.

The eyes are not difficult to account for, as plenty of Annelids have eyes at the extreme anterior end of the ventral cord, in connection with the first ganglion.

To refer, in passing, to another structure. The Vertebrate notochord has been shown by Ehlers and Eisig to correspond with the "*Nebendarm*" of Annelida. At the risk of being pronounced a heretic, I venture the opinion that the swimming-bladder of fishes is also a derivative of the "*Nebendarm*," and that the notochord and swimming-bladder are parts of the same structure which have acquired different functions, and so developed divergently. It is certainly not difficult to raise arguments against the so universally accepted homology of swimming-bladder and lungs.

And now let me refer to some recent results of my own on the Vertebrate nervous system. I have depicted them, very diagrammatically, in the accompanying figure. It represents a



Diagrammatic transverse section through the trunk region of a Vertebrate embryo. *Ep*, epiblast; *Z*, *Zwischenstrang* of Prof. His; *Sp.Gl.* spinal ganglion: *Sp.c*, spinal cord; *So*, somite; *N*, notochord; *C.G.*, ciliated groove of ventral surface of spinal cord; *Ac*, gut.

transverse section through the trunk of a very young Vertebrate embryo, say a lizard; and it is designed more especially to show the nervous system. The neural tube (*Sp. C.*) is an open plate, the two sides of which are folding together; above it are seen laterally two small outgrowths (*Sp. Gl.*) not connected with the neural tube, and which have been split off from the neighbouring skin or epiblast (*Ep.*); they are growing out from the skin, and will soon be segmented off from it to form the spinal ganglia. It has usually been supposed that the cranial and spinal ganglia of Vertebrates arise as outgrowths of the central nervous system. Such is not the case; the diagrammatic figure given above partially disproves that, and it would be easy to give a series of figures which would demonstrate beyond doubt that the spinal ganglia and certain portions of the more complicated cranial ganglia arise from the epiblast outside and beyond the limit of the central nervous system, and that not a single cell of either cranial or spinal ganglia is derived from the latter. Now, the mode of development of the ganglia in Vertebrates tallies exactly with that described by Kleinenberg in Annelida for the parapodial ganglia. These latter also arise as epiblastic differentiations just above the lateral limit of the ventral cord, and, like the ganglia of Vertebrates, they appear segmentally.

Here, then, is one point of close resemblance, and not an unimportant one, between the Annelid and the Vertebrate.

Having got thus far, one is tempted to study the development of the central nervous system of Vertebrates more closely, in order to see whether other Annelid peculiarities recently discovered are represented. Of such, two have presented themselves, and while probably but the forerunners of a series yet to be unravelled, they are in themselves of the highest significance. I have represented these in the diagram in such a form that they may be easily understood; but be it remarked that they do not appear so obviously till at a later stage than that depicted.

Evidence has long been wanting of a bilateral origin of the central nervous system of Vertebrates (no doubt it is a bilateral structure—everyone, except perhaps Prof. Hubrecht, believes that), and if it is comparable to the ventral chain of Annelids, it ought to show traces of such origin in its early development. It is precisely this which I believe to have discovered.

Even before the actual closure of the two limbs of the neural plate occurs (a phenomenon which takes place much later than is generally supposed) the neuro-epithelium of the one limb does not pass directly into that of the other limb, for the two are separated below by a tract of non-nervous epiblast having the characters of a ciliated epithelium (*C.G.*). Thus, with greater truth than one can speak of the absence of primary connection between ganglia and central organ, it must be admitted that the two lateral halves of the central nervous system itself are at first destitute of nervous connection with each other. This ciliated groove (*C. G.*) is a very obvious structure in transverse sections of great numbers of Vertebrate embryos. Curiously enough, I cannot find it figured by any embryologist except His, and he does not say anything about it.

The peculiarities just described (a developing nervous apparatus composed of two bands of neuro-epithelium separated from each other by a ciliated groove) are eminently characteristic of Annelids. Nay, more; Kleinenberg states that the ciliated groove takes its origin from a double row of cells in the mid-ventral or neural line, and I am of opinion that such is the origin of the ciliated neural groove of Vertebrates. If this discovery of the double nature of the neural plate has the significance which I claim for it, the generally accepted opinion as to its primary structure must fall to the ground. The neural plate is usually supposed to be composed of two layers—an inner nervous one, and an outer ordinary non-nervous one; the inner layer is supposed to give rise to the nerve-cells, &c., while the outer epiblastic one, having unfortunately got shut in with the tube formation, has nothing left to it but to form the ciliated canal.

Both these conclusions are wrong. Years ago, Altmann showed—and it has been confirmed scores of times—that it is just those cells next the primary central canal which increase most, and so form the antecedents of the ganglion-cells. The real truth is, that the greater part of the epithelium lining the primary (as opposed to the permanent) central canal is a neuro-epithelium, for only such a one has the faculty of producing ganglion-cells on its inner side.[1]

The epithelium of this ciliated groove having developed cilia, undergoes no further differentiation for some time; *it is the only part of the primary central cylinder which is ciliated, and which does not form ganglion elements, and hence it is the only part which is not neuro-epithelium.* It forms later, by the growth and increase of its elements, *most if not the whole of the ciliated epithelium of the permanent central canal.*

In one respect the ciliated groove of the Vertebrate differs from that of Annelids—it gets invaginated along with the central nervous system; and I am not aware that any Annelid is known in which the ciliated groove is removed from the outer surface of the body, along with the ventral cords.

Now these facts are very remarkable, and, taken in connection with other points previously mentioned—such as the formation of the notochord and swimming-bladder, the lateral sense-organs, the origin of the ganglia—they furnish us with a combination of Vertebrate characters for which a parallel is to be found in the Annelida, and in no other group.

Further, we have in the nephridia of Vertebrates a series of structures which, as Semper first showed, find their parallel in Annelids. When one considers recent advances in our knowledge of the nephridia of Annelida (more especially those we owe to Drs. Eisig and Ed. Meyer) in connection with the, as yet, partially unpublished researches of Dr. Van Wijhe on Vertebrates, the justice of Semper's and Balfour's renowned comparison becomes more and more obvious.

I have shown, in a former number of NATURE (vol. xxxvii.

[1] As I write this, there occurs to me a beautiful idea of Kleinenberg's, that the ganglion-cells in the central organ which are perceptive of light have that power in virtue of the fact that they were themselves once retinal elements or parts of such elements.

p. 224), in what a marvellous manner the development of the hypophysis cerebri of Vertebrates, with its oral and neural portions, accords with the development of the permanent œsophagus and its special nervous system in Annelids. I now submit some no less striking resemblances between the two groups; and I am of opinion that we may hope, with work and increasing knowledge, to encounter many more such, as yet undreamt of.

J. BEARD.

Anatomisches Institut, Freiburg i/B., September 21.

THE JOURNAL OF THE ROYAL AGRICULTURAL SOCIETY.[1]

IT is seldom that the Journal of an important Society so abounds with obituary notices of prominent contributors as the one now before us. The sad refrain of "*In Memoriam*" runs through but too many of the closing pages of the number, in affectionate remembrance of names which have been associated with the advancement of agricultural knowledge throughout a considerable part of this century. The late Charles Randell, of Chadbury, was essentially a farmer of the widest views and experience, and full of sympathy for scientific work. The late John Chalmers Morton, the late John Algernon Clarke, and the late John Coleman ranked among the most distinguished ornaments of the literary aspect of agriculture. The editor, remarking upon these losses, says: "It is a noteworthy but melancholy circumstance that, in the short space of six months, the three leading professional writers on agricultural subjects should have been gathered in by the Great Harvester." We should be wanting in respect to pass over unnoticed these bereavements, and when we call to mind the very recent deaths of Dr. Voelcker and Mr. H. M. Jenkins, the late secretary and editor, we must admit that this Society has sustained exceptionally heavy losses.

The present number, however, bears witness to the fact that able successors are to be found to carry on the good work of the Society, and that, as the veterans pass away, young and enthusiastic labourers step into their places.

As usual, the material of the half-yearly issue may be divided into official Reports and articles by unattached contributors. The first section includes the Reports on the farm prize competition in Northumberland; on the implements, live stock, and poultry at the Nottingham meeting of last summer; on horse-shoeing, followed by an able paper on the structure of the horse's foot by Prof. G. T. Brown, C.B.; and on the Newcastle (1887) engine trials, by the Consulting Engineer to the Society. These Reports we cannot do more than notice as well worth the attention both of mature agriculturists and students of the art. The remaining portion of the volume contains articles upon the principles of forestry, farming in the Channel Islands, the propagation and prevention of smut in oats and barley, and various papers on stock-feeding and crop-growing.

None of these papers will create more interest than that upon the herbage of old grass-land, by Dr. W. Fream, and this paper stands prominently forward as the only one which may be described as an original investigation. The question is not only important, but controversial. The best way of producing that inimitable natural product, a rich pasture, has long been a subject of vital interest to landowners. In the long period of agricultural depression, grass-lands have scarcely shared in the general depreciation of values. Good grass-land will always let, and it is likely to maintain its value. The difficulty of converting tillage land into grass has always, however, been a problem hard of solution, and anyone who throws light upon this question is deserving of gratitude.

One of the chief difficulties has consisted in ascertaining the proper descriptions of seeds for producing a permanent pasture, and a great deal of discussion has taken place upon the relative merits and demerits of the members of the large family of the *Gramineæ*, as well as of the *Leguminosæ*, composing the complex herbage of a good meadow or pasture. Certain grasses have been named as especially suitable, while others, although occurring in all pastures, have been condemned as worse than useless. On the other hand, it has been freely asserted that many of our best grazing-lands are largely composed of grasses which have been stigmatized as worthless by certain authorities, and the inspection of high-class pastures has often staggered the botanist by the perverseness with which which they carried the "wrong" descriptions of grasses, and nevertheless held their own as producers of valued hay, or, if grazed, of beef, mutton, and milk.

[1] Second Series, vol. xxiv. Part 1. (London: John Murray, 1888.)

One of the most maligned of the grasses of late years has been common rye-grass. This grass, although popular with farmers, was stigmatized by Mr. Faunce de Laune, in an able paper published a few years ago, as a short-lived and inferior grass, foisted upon the farmers by seedsmen because of its cheapness and the ease with which it germinated and covered the ground. Mr. Faunce de Laune *ruined* rye-grass, his views being somewhat too precipitately indorsed by the officers of the Royal Agricultural Society, and the seed trade was ruled into unwilling obedience. Rye-grass was banished from all mixtures sown by truly enterprising and advanced agriculturists, but its use still lingered among the less scientific but more practical members of the confraternity of farmers.

In spite of this crusade against rye-grass, many observing and scientific agriculturists were in doubt, especially as rye-grass was seen to occupy a leading position in all natural pastures, and hence its evanescent or short-lived character was doubted.

Prof. Fream, partly from a desire to test the true value of rye-grass, but also with a view to investigating the botanical composition of good grass-land, put himself in communication with a number of experienced agriculturists in England and Ireland, and with their co-operation transplanted twenty-five representative sods, 2 feet long, 1 foot broad, and 9 inches deep, from as many pastures, and planted them side by side in a bed 72 feet long and 6 feet wide in the Botanical Garden of the College of Agriculture, Downton. This transplantation was accomplished in the winter and spring of 1887-88.

In the month of July the herbage of each turf was cut, and submitted to a quantitative botanical examination, with very interesting and surprising results. In the first place, these samples of pastures, brought from twelve English and eight Irish counties, gave evidence that the preponderance of their herbage was composed of two plants, one being the maligned and tabooed perennial rye-grass (*Lolium perenne*), and the other chief constituent being common white clover (*Trifolium repens*). As each of the twenty-five sods was selected from the best grass-land of its district by resident agriculturists of well-known judgment, the case appears to be conclusive in favour of the recently, but only recently, discarded grass. The actual fact is that rye-grass constituted in the various plots high percentages of the total gramineous herbage, as the following figures show:—No. 1 turf (Wainfleet), 75 per cent.; No. 2 turf (Tenterden), 90 per cent.; No. 3 turf (Sherborne), 76 per cent.; No. 4 turf (Sherborne), 77 per cent.; No. 5 turf (Somerset), 82 per cent.; No. 6 turf (Derbyshire), 18 per cent.; No. 7 turf (Somerset), 90 per cent.; No. 8 turf (Tipperary), 66 per cent.; No. 10 turf, 78 per cent.; No. 11 turf, 83 per cent.; No. 12 turf, 90 per cent. It is needless to continue this list, and it is sufficient to say that, with very trifling exceptions, these important turfs unanimously showed themselves in favour of rye-grass; in fact, this species heads the list in 21 out of the 25 cases.

Similarly, the leguminous herbage was found to contain one constituent in paramount abundance—namely, white clover; so that it may be approximately stated that, while the grassy herbage was chiefly composed of rye-grass, the leguminous herbage was chiefly composed of white Dutch clover. In one case—that of a turf sent by Sir Louis T. Delcomyn, of the Old Court, Bradwardine, Herefordshire—rye-grass and white clover composed the entire herbage, without the intervention of another plant of any kind whatsoever.

A more crushing piece of evidence against the enemies of perennial rye-grass could not well have been produced, and the farmer will once more be justified for his slowness in accepting the *dicta* of some of his would-be teachers. The case is of such practical importance that we have dealt with it at some length; and it should be added that the percentage botanical composition of the gramineous herbage of each turf is given in detail, so that the labour involved must have been very great.

Prof. Curtis, in a useful paper upon Forestry, deprecates the founding of a School of Forestry, but recommends the formation of a representative Board of Examiners in Forestry on the lines proposed by Mr. Rogers, of the Surveyors' Institution, and Colonel Pearson, to the Select Committee on Forestry. The Report on the Farm Prize Competition is of value for comparative purposes, chiefly as showing the amounts expended by good farmers upon fertilizers and feeding-stuffs, and the different practices obtaining in the locality where the competition took place. The remaining papers we cannot at present notice particularly, but have indicated their presence.

A RELIC OF ANCIENT MEXICO.

THE appearance of No. 1 of the *Peabody Museum Papers* marks a new departure in the publications of the Museum of American Archæology and Ethnology. Henceforth, Prof. F. W. Putnam states, the special papers, hitherto published in connection with the Annual Reports, will be issued in a separate but similar octavo form at irregular intervals, as the means for printing them is obtained. Part 1 of vol. i. of this new series, just received, consists of an interesting and thoughtful historical essay on a relic of ancient Mexico entitled "Standard or Head-dress," by Mrs. Zelia Nuttall, accompanied by three coloured plates. A quarto German translation by Dr. A. B. Meyer appeared in the last volume of the *Abhandlungen und Berichte des K. Zoologischen und Anthropologisch-Ethnographischen Museums zu Dresden.* It treats mainly of a remarkable piece of ancient Mexican feather-work inlaid with gold of the time of Montezuma, which was one of the first presents received and forwarded by Cortes to the Emperor Charles V. It subsequently formed part of the famous Ambras collection of historical armour, figuring in various catalogues of that collection as a "Moorish hat," an "Indian apron," and a "Mexican head dress," and is now preserved in the Imperial Natural History Museum of Vienna. It was carefully restored by the late Prof. F. von Hochstetter, who published in 1884 a description of it as a "banner" or "fan-shaped standard," basing this identification chiefly upon the resemblance it presented to a "fan-shaped object" depicted behind the portrait of a Mexican warrior in the "Bilimek" collection acquired by the Museum in 1878. In the present essay Mrs. Nuttall adduces abundant testimony that the feather piece in question was a head-dress which formerly presented all the attributes of colour, form, and insignia of the war-god Huitzilopochtli, the hero-god and totemic divinity of the Mexicans. Such head-gear could have been worn only at the time of the conquest by Montezuma, "the living representative of the god," as "supreme pontiff and chief warrior." An exactly similar emblematic head-dress, she points out, is depicted on the so-called "sacrificial stone" as worn by Jiz-oc, one of Montezuma's predecessors. It is further maintained that the painting of the "Bilimek" warrior must be regarded as a rebus and not as a portrait. The "fan-shaped object" is the insignia of Quetzal feathers, characterizing the high rank of the warrior, who was also a priest, and is represented as clad in a human skin. The house = *calli*, piece of cord = *mecatl*, and arrows = *tlacochtl*, similarly depicted, yield, together with the Quetzal feather insignia when deciphered with the aid of the associated complementary sign, the phonetic values: (1) the surname *Calmecahua*; (2) the title *Tlacochcalcatl* = lord of the house of arrows or supreme war-chief; and (3) the tribal designation *Quetzalapanecatl*, a native of Quetzalapan, a locality near Mexico conquered by the Mexicans in 1512. This renders probable the identification of the individual as that Calmecahua, or lord of the *calmecac*, who, as Diaz relates, "fought like a lion on the side of the Spaniards" at the battle of Otumba against his natural foes the Mexicans, and was afterwards baptized as Don Antonio, and is cited by Txtlilxochitl as the author of a history of Tlaxcala, written in 1548. However this may be, it is evident that he was a *pilhua*, or head of a large family, as Mrs. Nuttall shows that the heads, surmised by Dr. Hochstetter to be those of "decapitated enemies," painted at his feet, are the usual signs for enumerating individuals, by reference to other Mexican manuscripts extant, in which similar heads under a figure are accompanied by the Nahualtl word for genealogy, and in the case of a manuscript dating about 1520, in the possession of Mr. Bernard Quaritch, by the Nahuatl text in Spanish letters = "Tenancacaltzin these his sons' heads." In an appendix to this suggestive paper Mrs. Nuttall discusses the complementary signs of the Mexican graphic system.

SCIENTIFIC SERIALS.

Bulletin de l'Académie Royale de Belgique, October 1888.—On the influence of diurnal nutation in the discussion of the observations of α Lyræ, made at the Washington Observatory, by L. Niesten. In these researches, which are somewhat analogous to his previous observations on γ Draconis made at Greenwich, the author adduces a fresh proof of the existence of diurnal nutation. The coefficient resulting from his determination is 0·095″, giving 69° east of Paris as the longitude of the first meridian.—On a new registering process by means of photography, by Eric Gérard. In this ingenious apparatus, instead of using the voltaic arc as the source of the light falling on the concave mirror whose movements have to be recorded, the inventor employs the secondary spark supplied by the Ruhmkorff bobbin. This spark being periodical, owing to the elasticity of the check-spring of the bobbin, naturally gives the division of time in equal intervals inscribed on the registering curve. In this way the use of all special chronographs may be dispensed with. The author has applied the method to the study of the variable currents supplied by dynamos with alternate currents, and has obtained excellent results.—Jean Masius contributes a memoir on the genesis of the placenta in the rabbit, with a view to the elucidation of the difficult questions connected with the origin and purpose of various elements present in the fully developed placenta.

Rivista Scientifico-Industriale, November 15, 1888.—Granular snow and the theory of the formation of hail, by Prof. Ferdinando Palagi. The author had a good opportunity of studying the phenomenon of granular snow during a heavy snow-storm at Teramo on October 20. The grains, about the size of ordinary peas, were perfectly dry, falling with a clatter like that of hail, which they resembled somewhat in appearance, although evidently formed, not by superimposed layers of ice, but by particles of snow agglomerated under certain atmospheric and perhaps electrical conditions. They were relatively light, perfectly white and opaque, yielding under pressure between the fingers, and from their general appearance and the circumstances of their formation Prof. Palagi concluded that granular snow is the first phase in the formation of hail.—On the development of electricity from the evaporation of marine water under the exclusive action of the solar rays, by Prof. Luigi Palmieri. Some recent experiments with the Bohnenberger electroscope are here described, which fully confirm the conclusions already arrived at forty years ago by the author, and in fact anticipated by Volta, regarding the origin of atmospheric electricity from aqueous evaporation.—Signor Giuseppe Terrenzi describes some remains of the beaver (*Castor fiber*, Lin.) lately discovered in the Pliocene formations of the Colle dell' Oro near Terni.

SOCIETIES AND ACADEMIES.

LONDON.

Linnean Society, December 20, 1888.—Mr. W. Carruthers, F.R.S., President, in the chair.—Prof. R. J. Anderson exhibited a photograph of an apparatus for the microscope which he had designed, consisting of a revolving disk with clips, by means of which a number of slides may be successively brought opposite the microscope, which is fixed in a horizontal position in front of it.—Mr. Clement Reid exhibited fruit of the Hornbeam from the pre-glacial forest bed at Pakefield, near Norwich, and not previously recorded as occurring in any British deposit.—Mr. T Christy exhibited a collection received from Java of hairs from the base of various ferns, notably *Cibotium Cummingii*, and a species, as supposed, of *Dicksonia*, used as a styptic, for staunching blood. Prof. Stewart, in pointing out that the use of similar material for a like purpose in China was well known to surgeons, took occasion to explain the nature of the so-called "lamb of Tartary," on which an instructive little volume had been published by the late Mr. Henry Lee, F.L.S. Mr. D. Morris remarked that the use of "fern hairs" was also known as a styptic in South America, whence specimens had been forwarded to the Herbarium at Kew.—A paper was then read by Mr. D. Morris on the characteristics of plants included under *Erythroxylon Coca*, Lamarck, with a description of a new variety, which he proposed to name, from its origin, *E. novo-granatense.* He pointed out that the well-known coca-plant had been noticed by botanists and travellers for the last 300 years; and that, although Clusius was generally regarded as the earliest writer on it, he had been anticipated by Nicholas Monardes in his "Historia Medicinal," published at Seville in 1580, and translated by Clusius, who printed it in a condensed form in his "Exoticorum libri decem" in 1605. The plant was first described as a species by Lamarck, in the "Encyclopédie Méthodique" in 1786, from specimens brought by de Jussieu from Peru. Until lately the leaves had been used merely as a nervous stimulant, like opium in China, and betel in the East Indies; but had latterly come into prominence as the source of cocaine, a valuable alkaloid possessing anæsthetic properties in contact with the mucous membrane. There were several climatic forms more or less distinct; and after describing the typical plant, Mr. Morris pointed out the characters by which *E. novo-granatense* might be distinguished. The paper was ably criticized by Mr. J. G. Baker, Mr. Rolfe, and Mr. Thomas Christy.—Mr. Spencer Moore

contributed a paper on *Apiocystis*, which he regarded as a *Volvocinea*. The ciliated form was described, and it was shown that its zoospores may sometimes escape as cœnobia, like a degenerate *Volvocinea* which has exchanged the motile for the fixed condition. The sexual cells being zoogametes, its affinity is rather with *Pandorineæ* than with oogamous *Volvoceæ*. The paper was criticized by Mr. A. W. Bennett and Prof. Marshall Ward, who, while testifying to the importance of the investigation, expressed the hope that no change would be made in classification until further examination had been made of some of the stages at a critical period of development. Mr. George Murray gave his warm support to the views expressed by Mr. Moore.—A paper was then read by Mr. G. B. Sowerby embodying descriptions of some new species of shells, of which coloured drawings were exhibited. Amongst these, the most noticeable were an *Orthalicus* from the Peruvian Andes, *Pleurotoma* (Hong Kong), *Amathina* (Mauritius), *Crassatella* (Japan), *Clavigella* (Mauritius), and *Pectunculus* (Australia). An interesting discussion followed, in which Prof. Stewart and Prof. Mivart took part, upon the coloration of Mollusca being possibly dependent upon the colour of their natural surroundings, or upon that of the host to which in many instances they were found to be attached.
